Ad infection of cultured cancer cells, respiratory epithelial cells, hepatocytes, and antigen-presenting cells activates the NF- κ B and MAP kinase pathways.⁵⁴⁷ Induction of IL-6 and IL-8 does not require Ad gene expression and likely occurs via interaction of the virion with integrins on the cell surface. A biphasic mononuclear cell response in the cotton rat suggested an early appearance of monocytes and NK cells followed by specific T and B lymphocytes. The cell infiltrate was changed from a mononuclear to a polymorphonuclear leukocyte response by deletion of the Ad E3 anti-TNF genes (*14.7k*, *rida*, *ridb*). Deletion of the anti-MHC Ad E3-gp19K protein increased the intensity of the inflammatory response in the cotton rat but not in the mouse.^{227,676} These observations suggest that immunopathology plays a role in the host response to Ad infection, and this process is ameliorated by the E3 inhibitors of the host inflammatory response.^{227,574} Another Ad protein, the L4-100K protein, which is expressed at late stages of infection, inhibits granzyme B-mediated death by CTL.¹⁶ Thus, it is not clear at this point whether the cell-damaging effects of Ad infection or the host immune responses to the

FIGURE 56.6. Complex blood-borne protein and cellular factors interact with helper-dependent adenovirus (HDAd) vector within minutes of systemic administration (bottom). The cascade of inflammatory mediators initiated by the immediate cellular interactions (**middle**) exacerbates the clinical manifestations shown (**top**) over several hours. The induction of innate immune responses initiated days earlier leads to activation of antigen-presenting cells and subsequent T helper (Th) 1/2 cell expansion and an antitransgene humoral immune response to the virus and transgene. (From Seiler MP, Cerullo V, Lee B. Immune response to helper dependent adenoviral mediated liver gene therapy: challenges and prospects. *Curr Gene Ther* 2007;7:297–305.)

pathogen are responsible for the tissue pathology and clinical manifestations.

Induction of type I interferons (α and β) is part of the innate response to Ad infection. Ads have at least two mechanisms to counteract these interferons (see Chapter 55). First, the E1A proteins block the assembly of interferon-induced transcription factors, and second, VA-RNA₁, a 159-nucleotide RNA, binds to the protein kinase named PKR, prevents its activation by double-stranded RNA, and thereby prevents PKR from phosphorylating eukaryotic initiation factor eIF2 and shutting down protein synthesis.

Neutralizing and nonneutralizing antibodies are discussed in the section, Description of Key Antigens. After infection, most patients develop both group- and type-specific antibodies to the infecting Ad strain. Group-specific antibodies are not neutralizing of viral infectivity but are useful in measuring patient response when infection with an Ad is suspected but no isolate was obtained. In this case, acute and convalescent sera taken several weeks apart may demonstrate rising antibodies to a group-specific Ad antibody such as that measured by CF, IF, or ELISA, using a viral-infected tissue culture extract or purified hexon from a single Ad type. Type-specific antibodies are measured by either the neutralization test or inhibition of HA, as described in the section Viral Serology. It is clear that patients may continue to shed Ads intermittently, especially in their stools, for many months after a successful humoral immune response has occurred.²⁰⁵ Neutralizing antibodies may be protective against disease manifestation in the previously infected host or against reinfection with the same serotype, but they do not eliminate the carrier state.

Recent studies have begun to define the T-cell response to Ad infection in humans and Ad (see the section on Description of Key Antigens) (reviewed in^{382,409,762}). Although most of the early work in humans described Ad-specific CD4⁺ T cells, recent studies have detected and characterized Ad-specific CD8⁺ T cells. These CD4⁺ and CD8⁺ T cells are frequently cross-reactive among Ad serotypes, and many of the epitopes have been mapped to the conserved regions of hexon.

Although it is not known if these T-cell epitopes are protective against Ad in humans, most likely T cells in general are protective because the absolute lymphocyte level and the CD4⁺ T cell level correlate inversely with Ad infection and disseminated adenoviremia in immunosuppressed transplant patients (see section on Diseases Associated with Immunocompromised Patients). For example, in adult stem cell transplant recipients, clearance of human Ad viremia coincides with emergence of a coordinated CD8⁺ and CD4⁺ T-cell response against Ad hexon epitopes.^{199,277,813}

Although donor lymphocyte infusions can be used in hematopoietic stem cell transplant recipients with Ad infections to improve infectious diseases outcomes, potentially life-threatening graft-versus-host disease (GVHD) may develop.¹²⁵ Adoptive transfer of CTL against Ad can rapidly reconstitute anti-Ad immunity after stem cell transplantation without causing GVHD.^{199,277,410,813} Methods are being developed to activate and expand T cells *in vitro*, and these interventions appear to be a promising potential therapy for immunocompromised patients with serious Ad infections (reviewed in^{5,367,409,412,474,813}).

Virulence

It is not known why certain serotypes characteristically cause disease in some organs and not in others. Tissue culture experiments and the existing animal models do not explain the mechanisms of such tissue tropism or organ-specific pathogenicity. There is nothing obvious about the bioinformatics analysis of multiple Ad genomes that explains differences in pathogenicity, although most differences among species are in the E3 region.¹⁴¹ Because most Ads can attach to the CAR receptor, it is unlikely that this receptor can explain differences in the *in vivo* tropism of the various serotypes. Even the oral vaccine strains used to prevent respiratory disease in military personnel seem to depend more on physical formulation (i.e., enteric coating of a live virus so that it bypasses the oropharynx and first exposes the intestinal epithelium) than on mutation of virulence genes.⁴⁴⁶

EPIDEMIOLOGY

Human Ad serotypes are generally not pathogenic to animals, and animal Ads are pathogenic only within the species of origin.⁷⁰² However, simian species occasionally have been shown to have antibodies to human Ad12,³⁵³ and antibodies to simian Ads have been detected in human sera.¹⁸⁷ Recently, a novel Ad named titi monkey Ad, which caused a deadly outbreak of pneumonia and hepatitis in a closed colony of titi monkeys in California, caused a respiratory infection in a researcher in close contact with the monkeys, and this infection spread to a family member.¹⁰⁵ A screen of 81 random adult blood samples revealed neutralizing antibodies to this virus in 2 individuals. The native species for this virus is unknown. Of added interest, Ads isolated from great apes are phylogenetically related to human Ads in species B, C, and E, consistent with the possibility of interspecies spread at some point in time; however, frequent interspecies infections are unlikely.⁶¹⁴

In humans, transmission of Ad infection and disease varies from sporadic to epidemic. The pattern often correlates with the viral serotype and the age (children or adults) of the susceptible population. A virus watch study was undertaken in New York and Seattle,^{205,206} and much of the Ad epidemiology in civilian populations was learned from these studies, including that there was a high incidence of recurrent shedding, especially of the lower numbered serotypes, in fecal specimens. A large number of asymptomatic Ad infections were documented. Fecal–oral transmission accounts for most infections in young children.⁴³ Initial spread may occur by the respiratory route, but the prolonged carriage in the intestine makes the feces a more common source during both the acute illness and intermittent recurrences of shedding.²⁰⁵ The epidemiologic importance of the long latency in tonsil tissue is not known.

Ads are estimated to cause 8% of clinically relevant viral disease globally. They probably account for 3% of the infections in civilian populations and for about 5% to 10% if only febrile illnesses are calculated.^{205,206} The corresponding figures for young children are about 5% and 10%, respectively. In a recent PCR-based multicenter study, 4.4% of pediatric patients with diarrhea in Asia were shown to have Ad-positive stool samples, with Ad40 and 41 being the most prevalent serotypes.⁴²⁴ According to a survey carried out in Manchester, United King-

dom, 61.3% of patients with Ad infection were younger than 5 years of age, 24.2% were adults, and 5.6% were children between 5 and 18 years old.¹²⁶ The most prevalent serotypes were Ad2 (18.6%), Ad3 (14.9%), Ad1 (12.1%), and Ad41 (10.9%). While Ad2, 1, and 41 were isolated mostly from infants, Ad3 and, less frequently, Ad4 (8.3%) was recovered from adults.

Serologic surveys have furnished estimates of the prevalence of Ad infections. Early surveys indicated that antibodies to Ad1, 2, and 5 are most common and are present in 40% to 60% of children.^{27,73,317} The incidence of antibodies to Ad3, 4, and 7 is low at the same ages. These antibody results probably explain why adults are uncommonly infected with Ad1, 2, and 5 but are more susceptible to infections with Ad3, 4, and 7. During the surveillance for the virus watch studies, only about 75% of the Ad isolates were accompanied by an antibody response, as measured by the CF test.²⁰⁵

More recent surveys have provided additional epidemiologic information. Ad5 neutralizing antibodies have been found in ~80% to 90% of the population in Sub-Saharan Africa.^{1,36,106,167,301,332,459,533,693,710} In one study of sera from Africa, the seroprevalence of Ad5 was very high in neonates (93%, with 48% having neutralizing titers of greater than 1,000), and it correlated with maternal titers.⁷¹⁰ Interestingly, the seroprevalence was 13% in subjects aged 6 months to 1 year, was 28% at age 1 to 2 years, and then reached high adult levels at age 7. These data suggest that neonates acquired maternal antibody, which then declines following birth, but the children acquire new infections as they age.⁷¹⁰ Seroprevalence for Ad5 is 40% to 70% in Japan,^{301,754} ~85% in China (54% with neutralizing titers greater than 1,000),⁶⁹⁴ 70% to 80% in Brazil (with 14% greater than 1,000 neutralizing titers),^{187,459} nearly 100% in northern India with 25% of individuals having high neutralizing titers (greater than 1,000) and 31% having very high titers (greater than 10,000),⁵⁶⁷ and 82% to 94% in Thailand.^{36,459} In the United States, Ad5 seroprevalence ranges from 30% to 70% in various studies.^{25,36,108,301,459,533,627,754} In Europe, the seroprevalence of Ad5 is 50% to 60%.^{301,385,459,754} Ad6 (species C) is being evaluated as a vaccine vector^{263,776}; overall in the world, about half of subjects have neutralizing antibodies to Ad6, but mostly of low titer.^{138,459,624} For Ad2, which is closely related to Ad5 and Ad6 in structure and clinical properties, the seroprevalence was found to be 83% in one study of subjects from Philadelphia.²⁵

Seroprevalence studies have also been conducted for more rare serotypes, motivated in part because of considerations to use these serotypes as vectors. For Ad35 (species B), the seroprevalence was estimated to be between 0²⁵ and 10%^{36,533,754} in the United States, less than 10% in Europe,^{385,754} ~15% in Japan⁷⁵⁴ and Thailand,³⁶ and ~3% to 20% in Sub-Saharan Africa.^{36,385,533} With Ad11 (species B), seroprevalence is 10%⁷¹⁰ to 30%^{1,301} in Sub-Saharan Africa and Japan. Ad26 (species D) seroprevalence is 10% (with low titers) in the United States^{106,459}; 44% in Brazil¹⁸⁷; 10%¹⁰⁶ and 50% in Thailand⁴⁵⁹; and ~20%,¹ ~50%,^{36,459} and 60% to 80%¹⁰⁶ in Sub-Saharan Africa. Thus, Ad26 is not a rare serotype. Ad49 and Ad50 are rare in most areas of Sub-Saharan Africa, but Ad48 is more common in East Africa.^{1,36,710} With Ad36 (species D), which has been linked to increased obesity, neutralizing antibodies are rare in the United States and Thailand but were found in about half the population in Brazil and parts of Sub-Saharan Africa.⁴⁵⁹ The Ad28 seroprevalence is less than 10% in the United States.³⁴⁷

It should be noted that the serologic studies described previously refer primarily to neutralizing antibodies. Generally, the prevalence of total antibodies against the Ad is higher. Further, nearly all adult humans contain T lymphocytes, primarily CD4+ but also CD8+ specific for Ads.^{84,106,320,322} These T-lymphocyte analyses do not identify the serotype (by definition) to which they are specific, and the T lymphocytes appear to be broadly reactive because of cross-reactive epitopes (often on hexon).

The epidemic forms of Ad disease were studied in different ways from the sporadic endemic occurrences. The epidemics of ARD were well known during World War II, and this awareness preceded the isolation and the characterization of the first Ad by about one decade. This ARD, which occurred almost exclusively in recently assembled military recruits, was most common in winter. It did not occur in senior personnel in close contact with the recruits and was later identified as an Ad4 or Ad7 infection in most outbreaks (reviewed in^{287,575}). This disease rarely occurred in similarly congregated college students, suggesting that additional factors, such as more crowded sleeping conditions or the fatigue associated with basic training, contributed. The observation that ARD-causing Ads did not spread to civilian personnel in contact with the military supports these conditions as co-factors. In recruits congregated during the summer months, ARD often did not occur until the onset of colder weather in the fall. Influenza A could be distinguished because it affected both experienced and new recruits. Ad-induced ARD often affected 80% of the recruits, with 20% to 40% hospitalized. The duration of infectivity was rather short; virus was not demonstrable after 4 days of illness.⁶¹² Controlled studies of routes of infectivity for the ARD-causing Ads have demonstrated that aerosolized virus inhaled into the lungs of volunteers produced the disease, whereas application to the mouth, the nasal mucosa, or the intestine in enteric-coated capsules failed to produce the lower respiratory disease.¹²⁹ ARD outbreaks were effectively controlled by vaccination of recruits in the first few days of military service; however, recent interruption in the supplies of Ad vaccine has resulted in the reappearance of the epidemic form of ARD. This is discussed further in the section on Adenoviruses as Vectors for Vaccination and Gene Therapy.

The epidemiology of pharyngoconjunctival fever and keratoconjunctivitis, both of which may occur in epidemic proportions, is described later with the individual disease entities. Infection resulting in several of the Ad syndromes can be acquired in hospitals and can be spread as nosocomial infections.

CLINICAL FEATURES

Ads can commonly infect and replicate at various sites of the respiratory tract as well as in the eye and gastrointestinal tract. Less frequently, Ads can infect the urinary bladder and liver. On occasion, these viruses may also cause disease in other organs, such as the pancreas,⁵²⁴ myocardium, or central nervous system, which may be involved in meningoencephalitis. Although there are at least 57 distinct human Ad serotypes, most human disease is associated with only one-third of these types.⁵⁹⁵ Many Ad infections are subclinical and result in antibody formation that probably is protective against exogenous reintroduction of the same Ad serotype. However, the virus itself may be grown, especially from the gastrointestinal tract²⁰⁵ and respiratory tract,¹⁸⁹

for months after the initial infection and immune response. The more common illnesses associated with various Ads are described in Table 56.1 and in the following paragraphs. The association of Ad with the disease in question is often attributed to the detection of the virus or antibodies to the virus in the blood, or to the detection of the virus in specific tissue. Often very sensitive techniques are used such as nested PCR. It is important to bear in mind that the presence of the virus or viral DNA in clinical specimens does not necessarily imply a cause-and-effect relationship between the virus and the disease, especially when PCR or nested PCR has been used. We do not understand whether and how Ad persists at very low levels in humans, so it is possible that the detection of Ad is merely a coincidence. On the other hand, the detection of the virus should not be disregarded.

Respiratory Diseases

Endemic Adenovirus Infections of Young Children

About 7% of upper respiratory tract infection cases in children younger than 5 years of age are due to an Ad.⁵⁵⁷ The usual symptoms include nasal congestion, coryza, and cough. Other patients may have an exudative tonsillitis that may be clinically indistinguishable from disease caused by the group A streptococcus. The respiratory symptoms are often accompanied by systemic manifestations, such as generalized malaise, fever, chills, myalgia, and headache. The common serotypes are Ad1, 2, 5, and 6 (species C or HA group III) and occasionally Ad3 and Ad7 (species B or HA group I), which are endemic in most populations. Sporadic cases may be indistinguishable from other viral respiratory infections, such as influenza, parainfluenza, and respiratory syncytial virus.⁵⁵⁷ If conjunctivitis accompanies the signs and symptoms already described, the disease is designated as *pharyngoconjunctival fever*. The Ad serotype most commonly involved is Ad3, but Ad7 and Ad14 within the same HA group have been isolated from such patients.³⁰⁸

Ads also cause lower respiratory tract infections in children and are probably responsible for about 10% of the pneumonias of childhood.^{455,557} Most patients recover, but some epidemics have resulted in considerable mortality. Sequelae in those who recover may include bronchiectasis that can clinically manifest years after the primary infection. Ad7, in particular strain Ad7h in recent years, has been a problem in South America for pediatric lower respiratory tract infections.⁸⁷ In one retrospective study in Buenos Aires, Argentina, Ad7h was associated with 29 (2.4%) of 1,233 cases (mean age 8.8 months) with a mortality rate of 34.5% between 1984 and 1988.⁴⁹⁷ In another study of 22 cases in 1991–1992 in Buenos Aires, Ad7 was found in 82% of patients (12 of 14 were Ad7h) and species C in 18% of patients.⁸⁷ Four patients died, three of whom had Ad7h. In a similar study in Uruguay in 1994–1998, 32% of pediatric patients (mean age 8.8 months) had species B (all but one Ad7h) and 61% had species C.²⁰⁸ In a Taiwan study in 1999–2000, nine children (mean age 22 months) had Ad3, one had Ad2, and one had Ad11.¹¹⁵ In a U.S. study, there was a 6-month outbreak of Ad30 (species D) in a neonatal intensive care unit that involved 21 of 333 patients (6.3%) and that had pneumonia in 8 patients.¹⁹⁰ Six infants died, and death was associated with pneumonia.

Acute Respiratory Disease in Adults

In adults, the serotype subspecies B1 Ads (Ad3, Ad7, Ad16, Ad21, and Ad50) and species E (Ad4) are commonly associated with acute respiratory disease, whereas subspecies B2 viruses

(Ad11, Ad14, Ad34, Ad35) are more frequently associated with urinary tract and opportunistic infections in immunocompromised patients. Without significant circulation in North America, Ad14 emerged as a significant cause of acute and sometimes severe acute respiratory disease in 2006. Initially, the infection was recognized in three military bases under continuous systematic surveillance,⁴⁷¹ but widespread outbreaks were demonstrated shortly thereafter in Washington, Oregon, Alaska, Wisconsin, and Pennsylvania, and to a lesser extent in other states.^{92,93,188,313,350,421,441,701} The DNA sequence of the prototype Ad14 (de Wit strain, isolated in 1955) was published recently.⁶⁴³ Sequencing of the outbreak strain *elA*, *hexon*, and *fiber* genes suggests that Ad14p1 arose from recombination among similar Ad11 and Ad14 ancestral strains. A deletion of two amino acids in the knob region of the fiber protein is the only identified unique characteristic of Ad14p1.³⁵⁰ Low antibody titers against Ad14 in recruits sampled at admission to training camp and initial detection of Ad14p1 in cities on the U.S. West Coast that represent major ports of entry into the country from Asia suggest that travel and commerce played a major role in the introduction of this rare Ad subspecies B2 virus into the United States.^{350,701} Current studies are ongoing to better understand why the virus resulted in significant morbidity and mortality in a small subset of infected individuals; in one of the earliest outbreaks, in Oregon, there were 29 hospitalizations with 7 associated deaths.^{350,421} During the investigation of this initial civilian outbreak, 67 cases of Ad infection were detected during the study period and 40 (60%) involved Ad14.⁴²¹ Of those with medical records available for review, most presented with fever and cough; 29 (76%) required hospitalization, 23 (61%) required supplemental oxygen, 18 (47%) required critical care, 9 (24%) required vasopressors, and 7 (18%) died. Older age, chronic underlying condition, low absolute lymphocyte counts, and elevated creatinine levels were associated with severe illness. In most instances, no epidemiologic link between cases could be established.^{188,421}

Acute Respiratory Disease of Military Recruits

In many respects, ARD is similar to the description furnished earlier of the respiratory infection of children. The syndrome is predominantly caused by Ad4 (92.8% in one study conducted in 2004–2006),²⁴⁴ and less commonly Ad7. After 2005, coincident with similar findings in the civilian populations, there was the simultaneous emergence of increased diversity of infections due to subspecies B1 serotype 3, 7, and 21 and subspecies B2 serotype 14.⁴⁷¹ ARD is a syndrome that frequently occurs under the special conditions of fatigue and crowding created soon after the induction of young military recruits (reviewed in^{308,575}). Some cases have had a fatal outcome from the pneumonitis that may accompany and complicate the other, milder respiratory symptoms. A significant increase in severe and fatal cases was seen recently with the emergence of Ad14 infections in two U.S. military facilities.^{471,518} On the other hand, recent retrospective studies of Air Force recruits with pneumonia at Lackland Air Force Base did not find evidence that Ad14 was associated with excess overall morbidity as compared to pneumonia due to other Ad serotypes.⁷⁵² Further aspects of this disease are discussed in the sections entitled Epidemiology and Vaccines.

Pertussis-Like Syndrome

The association of Ad infection with a pertussis-like syndrome has led to speculation that Ads can cause clinical whooping

cough.⁶⁸⁹ Ad5 was isolated from multiple organs of a patient with severe whooping cough with lymphocytosis that ended fatally.¹²⁴ Later data from a controlled study of 134 children with a pertussis-like illness and 101 healthy controls reported the common association of Ads with whooping cough symptoms.⁵⁰⁶ Ads have been isolated from other studies of respiratory tract infections including pertussis-like syndrome.^{195,586} However, there was no evidence that the Ads alone were responsible for the syndrome. The large number of Ad isolates may be due to conditions favorable for reactivation of latent viruses from tonsillar tissue during concurrent *B. pertussis* infection.⁵¹⁶

Infections of the Eye

An acute follicular conjunctivitis may occur as part of a respiratory-pharyngeal syndrome or as a separate entity.^{53,496} Both bulbar and palpebral conjunctival involvement may occur and affect both eyes. The disease is often accompanied by significant preauricular lymphadenopathy.⁴⁴ Complete recovery without sequelae is the most common result of this rather mild illness. The incubation period is usually 6 to 9 days, but it was as short as 2 days in experimental infections in volunteers.^{46,348} Epidemiologically, these infections can occur sporadically or cause disease in large groups of contacts. Family members may be affected. When the source is a swimming pool or small lake, large numbers of children and young adults may develop symptoms. Swimming pool conjunctivitis is probably most commonly due to Ads.²⁰⁷ Although the virus is isolated from the conjunctiva of affected individuals, it has not been isolated from water samples from putatively infected sources. The common-source water-borne outbreaks usually occur in summer and are caused by Ad3 and Ad7; however, other types, such as Ad1, 2, 4, 6, 9 to 11, 15 to 17, 20, and 22 (species B, C, D, and E and HA groups I, II, and III), have been associated with this syndrome.^{53,496}

In contrast to the milder form of ocular disease described previously and limited to the conjunctiva, EKC is a highly contagious and more serious disease. The clinical entity was first described before the isolation of Ads and occurred among German workers in the late 19th century.^{299,334} It was subsequently observed in shipyard workers in Hawaii and in the continental United States. “Shipyard eye” was probably transmitted in the medical facilities that cared for chemical and physical trauma to the eyes of the workers. After an 8- to 10-day incubation period, a follicular conjunctivitis with edema of the eyelids, pain, lacrimation, and photophobia began. Corneal subepithelial infiltrates often followed the initial conjunctival involvements.¹⁴³ The disease is often unilateral with preauricular lymph node hypertrophy. Occasionally, other lymph nodes were involved, and constitutional symptoms occurred, especially in children. However, most often the disease was limited to the involved eye and its draining lymph nodes. Corneal opacities in some cases lasted for several years and, uncommonly, would remain for longer periods. In some patients, the involvement slowly progressed to a hemorrhagic conjunctivitis that should be distinguished from the rapidly evolving acute hemorrhagic conjunctivitis associated with enterovirus 70.¹⁴³ In addition to viral inoculation during an ophthalmologic procedure such as tonometry, EKC has occurred as a late summer and fall epidemic in certain parts of Japan, Taiwan, and Vietnam. Ad8 was the original cause of EKC, but outbreaks of Ad3, Ad19, Ad34, Ad37, Ad53, and Ad54 (a novel hexon-chimeric intermediate Ad22,37/H8)

have also been described.^{18,23,47,97,103,327,360,365,561,699,704} Recent outbreaks of EKC between 1995 and 1997 were caused by a unique isolate, designated Ad8I, which has Ad9 sequences in the hypervariable region of the *hexon* gene that may have allowed the virus to escape pre-existing neutralizing antibodies to Ad8 in the population.²² Treatment of severe infections caused by Ad8 with *N*-chlorotaurine, an antimicrobial agent, shortened the duration of illness and was well tolerated.⁷⁰⁴

Ad4 has been recognized to cause a range of symptoms, from EKC to pharyngoconjunctival fever.¹⁹ Ocular infections by Ad4 were rare up to the 1960s, but beginning in the latter half of the 1970s Ad4 caused many worldwide outbreaks of conjunctivitis.²²

Acute Hemorrhagic Cystitis

Acute hemorrhagic cystitis, an illness occurring almost exclusively in boys and associated with Ad11, is characterized by gross hematuria.⁵³⁰ Its significance lies in the potential confusion with other, more serious diseases of the kidney (such as glomerulonephritis). This self-limited disease is usually not accompanied by fever or hypertension, and tests of renal excretory and concentrating functions have been essentially normal. Ad21, like Ad11, is a species B HA type I and can also cause hemorrhagic cystitis.⁴⁹³ In Japan, when acute hemorrhagic cystitis occurs in a boy between the ages of 6 and 15 years, an Ad isolation from urine or a rise in neutralizing antibody occurs in about 70% of patients.⁵³⁰ In comparable studies of hemorrhagic cystitis in the United States, only 20% of cases can be linked to an acute Ad infection, and for 60% of the total, the etiology remains unexplained.⁴⁹³

The other population that develops hemorrhagic cystitis is immunosuppressed transplant recipients. According to one study, Ad infections account for 3.9% of hemorrhagic cystitis among pediatric hematopoietic stem cell transplant (HSCT) recipients.²³⁵ Another study of mostly adult HSCT recipients found that Ad was associated with 9.8% of cases of hemorrhagic cystitis.⁴⁸⁶ Ad hemorrhagic cystitis in HSCT patients is more frequently associated with T-cell purging and was less common in patients with acute GVHD than other causes of hemorrhagic cystitis.⁴⁸⁶ In the kidney transplant population, Ad can also cause hemorrhagic cystitis with or without concomitant nephritis; such patients typically present with fever and often feel poorly.^{12,261,282,380,544} In some patients, it appears that the infection was introduced with the transplanted kidney.^{389,746} In addition to Ad11, two other species B serotypes, Ad34 and Ad35, were isolated first from renal transplant recipients. Ad34 was isolated from urine, whereas type 35 was isolated from kidney and lung tissue at autopsy.^{283,500} Although neither was accompanied by the symptoms of hemorrhagic cystitis, the Ad35 clearly contributed to the patient's demise from pneumonia. Ad34, 2, and 31 were isolated from allogeneic bone marrow, hematopoietic stem cell, and liver transplant recipients with hemorrhagic cystitis, respectively.^{485,632}

Meningoencephalitis

It is rare to isolate any of the Ads from either the cerebrospinal fluid (CSF) or the brain. However, several reports have directly demonstrated Ads in CSF (Ad3, 5, 6, 7, 7A, 12, and 26).^{113,166,364} One patient with malignant lymphoma, immunosuppressed by chemotherapy, had an Ad32 isolated from the

brain at autopsy.⁶⁰⁶ A patient with large B-cell lymphoma developed meningoencephalitis due to Ad7.²⁰⁰ Ad5 was cultivated from CSF in two immunocompetent patients, one with meningoencephalitis and the other with meningitis.⁶⁷⁴ A bone marrow transplant developed fatal subacute Ad meningoencephalitis.¹⁴⁰ A 12-year-old immunocompetent girl developed tubulointerstitial nephritis with acute renal failure, hepatitis, and meningoencephalitis following systemic Ad infection; she recovered with supportive care.¹⁸⁶ There are other cases of meningoencephalitis in which viral isolation from extraneural sites or antibody titer increases have been used to make a diagnosis, especially associated with epidemic Ad7 pneumonia in children.⁶⁶⁴ A case of sudden unilateral deafness was associated with an Ad3 infection of the nasopharynx.³³⁰

Gastrointestinal Diseases

Gastroenteritis, or inflammation of the stomach and small and large intestines, is characterized by fever, vomiting, and diarrhea. It is frequently caused by viruses, bacteria, or parasites. Viruses that cause gastroenteritis include rotaviruses, Ads, noroviruses, calciviruses, astroviruses, and Norwalk virus. Rotaviruses are the leading cause of diarrhea in the world, and calciviruses cause the most gastroenteritis outbreaks in industrial nations.²²⁹ The role of Ads is discussed in the next few sections.

Diarrhea

The relationship between Ads and diarrhea has had a long and complicated history but has now been clarified.^{308,787} Because many Ads replicate efficiently in the intestine and are excreted in the stool, it was assumed that they would be strong candidates for causing diarrhea. However, most earlier epidemiologic studies generally found as many Ad isolates in the stools of controls as in those with diarrhea.⁵⁷⁸ The failure to correlate Ad growth from stool with clinical illness was a good example that Ads should not be designated as the cause of a whole spectrum of medical illnesses just because they can be cultured from the stool of an individual with a disease. Asymptomatic children can clearly shed Ads in stool and often develop antibodies to the particular type grown.^{205,290} These subclinical infections probably result in lifelong immunity.

The whole issue of Ads as a cause of infantile gastroenteritis was re-examined based on the observation that initially "noncultivable" Ads were seen on EM examination of stool smears of affected children.²⁰¹ Serologic detection methods such as ELISA and alternate tissue culture host-cell systems, such as the HEK 293 line, have identified several of these "noncultivable" viruses.^{147,781} Two different enteric Ads, Ad40 and 41, have been associated with diarrhea.^{147,226,781}

Epidemiologic studies to assess the importance of these agents have been completed for several population groups. A report of 14 enteric Ad-related cases of diarrhea in 27 hospitalized patients studied during a 12-week period suggested that these viruses may be an important cause of acute gastrointestinal disease in hospitalized young children and may be nosocomially transmitted; this report also suggested that respiratory symptoms may be a prominent part of the clinical manifestations.⁸⁰² The incidence of Ad-related gastroenteritis differs considerably in the various studies and locations reported by many authors. In general, it is not as prevalent as rotavirus diarrhea, occurs most often in children younger than 4 years of age, and is not easily distinguished on clinical grounds from rotavirus

infection.⁵⁸⁷ In Bangladesh, it was responsible for 2.8% of the cases of diarrhea but reached 12.3% in some months as diagnosed by a monoclonal antibody specific for Ad40 and Ad41.³³³ In day care centers in Houston, 38% of 249 children present during 10 separate outbreaks had diarrhea associated with enteric Ads. Of these patients, 46% were asymptomatic, demonstrating that even during epidemics of enteric Ads, many infected children do not develop gastroenteritis.⁷⁴⁵ In another study, the prevalence of all Ads in stool was 8%, and Ad40 and Ad41 were 2% in both 565 patients with diarrhea and 129 controls.⁴²⁰ In a recent study of 44 infants in a day care center in Tokyo, Japan, Ad was found in 12.5% of fecal specimens from symptomatic and 11.5% from asymptomatic infants; one outbreak of acute gastroenteritis in these infants was linked to Ad12.⁶ In another recent study using ELISA analysis of 3,577 fecal specimens from infants and children with acute gastroenteritis in Japan, Korea, and Vietnam during 1998 and 2001, 4.4% were positive for Ad.⁴²⁴ More than half of these were Ad41, but Ad40, 2, 3, 8, and 31 were also detected. Enteric Ads were detected in a fraction of stool samples of children with gastroenteritis in a number of countries, as follows: 6.9% in the United States⁷²; 8.0% in Sweden⁷³⁵; 8.3% in Germany⁵³⁸; 7.9% in the East Anglia, United Kingdom⁶⁶⁵; 9% in Belfast, United Kingdom⁵³⁴; 1.4% in Blantyre, Malawi¹³⁵; 1.5% in Brazil⁶⁷³; 6.7% in Iran⁶¹⁹; 4% in Jakarta, Indonesia⁶⁹⁰; 10.8% in Shenzhen, China²⁷⁴; and 4% in Jakarta, Indonesia.⁶⁹⁰ In many of these studies, nonenteric Ads were also detected but at lower frequencies. In Japan and Iran, antibodies to enteric Ad were detected in sera from about half of healthy children analyzed.^{618,659} Thus, it is clear that the role of enteric Ads as a cause of diarrhea is roughly the same in different areas of the world.

Intussusception

Another intestinal syndrome, intussusception, has been linked in some patients to Ad infection.^{45,687} The telescoping bowel characteristic of intussusception may be caused by mesenteric adenitis acting as a lead point to the mechanical obstruction. Ads (species C, HA group III, Ad1, 2, 5, and 6) have been isolated from both stool cultures and the involved lymph nodes removed at surgery.^{122,571} The percentage of children with intussusception showing evidence of Ad is high as evidenced by shedding into stool, detection in throat swabs, anti-Ad antibodies, Ad inclusion bodies in tissue samples, and identification of Ad by electron microscopy. The percentages found in a number of studies range from 22% to 61% (see references in³⁰⁸). Most of the studies examined control patients, and in all cases the presence of Ad was statistically more significant than in the controls. These studies were from several parts of the world (United States, United Kingdom, Spain, France, Taiwan, Nigeria). In an analysis using immunohistochemistry and PCR of formalin-fixed intestinal specimens from 12 Mexican pediatric patients, 4 patients (33%) were positive for species C Ad.²⁵¹ There is no evidence that Ad40 and Ad41 are involved in this syndrome.⁵⁹ A proposed alternative explanation is that some hyperirritability of the small intestine might be caused by Ad infection and lead to the intussusception.⁸⁰⁸ However, many patients with intussusception have no evidence of Ad infection, and the disease is probably multifactorial. Ad inclusions have been seen in about one-third to one-half of appendices removed at surgery.³⁰⁸

Celiac Disease

Celiac disease is a common autoimmune disease thought to be caused by ingesting the proteins of the gliadin, hordein, and secalin classes found in wheat, barley, and rye. Structural homology between the Ad12 E1B-55K protein and A-gliadin, a major component of gluten proteins known to activate celiac disease, was noted. In addition, most patients with celiac disease had evidence of prior Ad12 infection, in contrast to matched controls. These observations raise the possibility that the E1B-55K protein from an Ad found in the intestine may play a role in the pathogenesis of celiac disease, perhaps by inducing cross-reacting antibodies to A-gliadin.³⁴⁶ In support of this possibility, T lymphocytes from celiac patients recognize a synthetic dodecapeptide shared by the Ad12 E1B-55K protein and A-gliadin.⁴⁵⁶ On the other hand, in three studies using PCR to determine whether there was persistent Ad12 infection in the intestinal mucosa of patients with celiac disease, 4 of 18 patients had detectable Ad12 DNA, as did 2 of 24 controls, leading the authors to conclude that Ad12 persistence is not a major element in celiac disease.⁴⁵¹ Similar conclusions were reached by others but do not preclude that prior Ad12 infection might have been involved in the evolution of celiac disease.^{407,753}

Myocarditis

Myocarditis is an inflammatory disorder of the myocardium characterized by necrosis of myocytes and infiltration of inflammatory cells. The most common form of this disease, viral myocarditis, is generally thought to be caused by enterovirus infection (e.g., coxsackievirus), although there is evidence that Ad may be a significant cause as well (reviewed in^{69,356,453}). Ads do not normally cause symptomatic infection of the heart, and the reason that it is associated with myocarditis and dilated cardiopathy is unknown. Both enteroviruses and Ads can infect cardiac myocytes in culture. It is of interest that coxsackieviruses and Ads both use CAR as the receptor to enter cells. CAR expression in healthy and diseased hearts is reported to be variable, and it has been suggested that this variability plays a role in enterovirus and Ad myocarditis.⁵⁷⁰

A number of reports have diagnosed Ad in myocarditis and dilated myocardiopathy. In a study of 126 conscripts diagnosed on the basis of serial electrocardiograph changes during an acute infection, Ad-specific antibodies increased in 19 patients, although most did not have myocarditis.³⁶² Ad DNA has been detected by PCR in myocardial biopsies primarily from children with acute myocarditis in three studies (see³⁰⁸). Although there was clinical and electrocardiogram evidence of myocarditis, most of the Ad-positive biopsies did not show classic inflammation, in contrast to those that appeared to be associated with enterovirus infection. In children with myocarditis or dilated cardiomyopathy, Ad was detected in anywhere from 8.1% to 36% of patients.^{67,68,83,397,621,626,657} Sequencing of the PCR products from one of these studies established that 80% of the Ad isolates were Ad2; most of the remainder were Ad5 and one was Ad6; nonfatal cases caused by Ad1 have also been described.⁶²¹ In another study of 142 Ad-positive patients with clinical diagnosis of myocarditis, 57 (40%) had histopathology that was consistent with myocarditis; none of the control patients were positive for Ad.⁶⁷ Some patients with detected virus remain positive for a prolonged period of time (mean of 6.8 months); clearance of the virus was associated with improved symptoms.³⁹⁷ Myocardial involvement with Ad may

be patchy, suggesting that biopsies may miss affected regions and thereby underestimate the incidence of Ad-associated disease.²⁶⁸ These studies suggest that Ad may be a cause of or a contributing factor for cardiomyopathy.

Ads may also be associated with idiopathic left ventricle dysfunction in adults. Ad DNA (mostly Ad2) was found by nested PCR analysis of myocardial tissue without evidence of myocarditis from 12 of 94 patients with this disease.⁵⁵⁶ This same group has conducted a phase II clinical study of interferon- β treatment of 22 patients with long-term cardiac dysfunction and with Ad (7 patients) and enterovirus (15 patients) persistence as detected by nested PCR analysis of myocardial biopsy specimens.³⁹⁶ Twenty-four weeks of interferon- β treatment was associated with viral clearance and improved left ventricle function in most patients.

Among heart transplant patients, the presence of Ad genome within biopsy specimens has been correlated with adverse outcomes in two independent studies.^{491,661} In the first study of 553 consecutive biopsy samples from 149 pediatric heart transplant recipients, 30 samples were positive for Ad.⁶⁶¹ Eighty-five percent of patients with positive PCR results had an adverse cardiac outcome within 3 months of the biopsy and just over a quarter had graft loss due to coronary vasculopathy, chronic graft failure, or acute rejection; the odds of graft loss were 6.5 times higher in those with a detectable virus by PCR.⁶⁶¹ In the second study, of 928 serial endomyocardial biopsies from 94 pediatric heart transplant patients, Ad genome was detected in 9.6% of patients. Presence of detectable viral genome by PCR was associated with decreased graft survival (2.4 years vs. 8.7 years in the PCR-negative group) and earlier development of transplant coronary artery disease.⁴⁹¹ For 2 years of the study, patients with detectable virus were treated with intravenous immunoglobulin (IVIG) and this intervention was associated with a trend toward improved graft survival ($p = .06$).⁴⁹¹

Adenovirus Infection During Pregnancy

A number of studies have established that the presence of Ad in amniotic fluid is more frequently associated with abnormal fetuses than normal ones. In one prospective observational study of second-trimester women undergoing either genetic amniocentesis or evaluation of fetal abnormalities, amniotic fluid was analyzed for Ad and other viruses by multiplex PCR.⁴¹ The prevalence of Ad was similar in women with normal (39/652) and anomalous (23/364) fetuses, but echogenic liver lesions with or without hydrops and neural defects in fetuses were more common with Ad.

Diseases Associated with Immunocompromised Patients

Although Ads are not nearly as prevalent as the various herpesviruses during immunosuppression, Ads have been isolated from immunocompromised hosts, in particular transplant patients, and have contributed to their morbidity and mortality (reviewed in^{98,197,328,434}). The precise incidence of Ad illness in transplant recipients remains poorly defined because available studies have incorporated different definitions of disease, have used different diagnostic techniques (culture vs. PCR vs. histopathology), and have evaluated diverse patient populations; large prospective studies have not been performed.³²⁸

In the stem cell transplantation (SCT) population, the incidence of disease ranges from 3% to 47%.^{30,80,100,202,256,295,399,435,655} Available data suggest that Ad infections are more frequent in allogeneic SCT recipients compared to those receiving autologous grafts (8.5% to 30% vs. 2% to 12%); children compared to adults (20% to 47% vs. 9% to 13.6%); patients who receive T-cell-depleted grafts (45% vs. 11%); and patients with acute GVHD.^{30,80,99,100,184,202,256,295,399,434,435,436,655} Severe lymphopenia (less than 300 cells/mm³) is associated with a progression to disseminated and often fatal disease.^{100,101,184,434,436} Likewise, T-cell depletion, through either the use of alemtuzumab or *ex vivo* T-cell depletion of grafts (i.e., CD34+ selection) or the use of cord blood, are associated with enhanced risk of Ad disease.^{355,501,592} In the SCT patient Ad can cause severe respiratory disease, hepatitis, colitis, hemorrhagic cystitis, adenoviral keratoconjunctivitis, and disseminated disease. Stem cell patients can also be divided into patients with subclinical viremia, viremia with disease symptoms, and disseminated disease. The incidence of disseminated disease is 1% to 7% with a reported mortality of 8% to 26%.⁴³⁴

Development of quantitative PCR (qPCR) assays in the past several years that are broadly reactive against many or all Ad serotypes have allowed important new insights into Ad infections and Ad-associated disease in SCT patients (reviewed in^{98,197,328,434}). These studies have led to suggestions on prediction and perhaps management of Ad-associated disease. In a retrospective study of 303 pediatric and adult patients who underwent allogeneic SCT, 35 (11.5%) were found using non-PCR procedures to have Ad infection (serotypes 1 [$n = 6$], 2 [$n = 7$], and 31 [$n = 4$] were the most common).⁶² In an analysis of 132 consecutive pediatric patients undergoing SCT, 36 (27%) were positive by qPCR for Ad in species A, B, C (78% of all positive cases), D, and F.⁴³⁵ Except for gastroenteritis in some patients with Ad in stool, the isolation of Ad from other sites (throat, urine) was not linked to disease and mortality was not different from patients that were negative for Ad. Ad was detected in the peripheral blood of 11 children, 9 with species C and 2 with species A, and 7 (82%) of these children died.⁴³⁵ With most of the children that died, repeated PCR testing revealed a 10-fold rising load of Ad in the peripheral blood with a median of 3 weeks prior to the onset of fatal outcome. The maximum virus load in the blood for those patients who died ranged from about 10⁴ to 10⁷ or more genome copies/mL. T-cell depletion *in vivo* by immunosuppression and T-cell depletion *in vitro* by CD34+ selection were risk factors for Ad infection.⁴³⁵

In a study of 86 consecutive bone marrow patients who received alemtuzumab (Campath; a monoclonal antibody against CD52) to deplete T cells, Ad was detected in 11 (18%) patients.²⁶ Five patients died of progressive Ad disease. The authors concluded that the severity of lymphocytopenia and the continuation of immunosuppression were risk factors for Ad-associated death. In a study of 155 consecutive pediatric allogeneic SCTs, 126 of whom underwent T-cell depletion, Ad (species A [43%], B [5%], C [21%], and F [43%]) was detected by qPCR and other methods in 26 (17%) patients.³⁵⁴ Death from Ad was closely associated with lack of T-cell recovery (to greater than 300 cells/ μ L) following immunosuppression.³⁵⁴ This link between T-cell levels and adenoviremia and death is in accord with work by Chakrabarti et al¹⁰⁰ and other researchers (see later). The importance of T cells was also found in a retrospective study of 328 consecutive pediatric patients with allogeneic

SCTs in which Ad was found in 37 (12%) patients, mostly in patients with greater than a 2-log depletion of T cells.⁷⁴⁴ Death occurred in seven of seven patients with Ad DNA in serum and decreasing lymphocyte counts. In another study, Ad infection occurred in 21 (44%) pediatric SCT patients and progressed to viremia in 6 patients who had low lymphocyte counts.²⁷⁶ Survival of these patients correlated with an increase in lymphocyte counts soon after the viremia, including Ad-specific CD4+ T cells, as well as neutralizing antibodies.

The SCT studies described previously were conducted on pediatric patients only. In an SCT study that included both pediatric patients and adults, Ad was detected in the whole blood by real-time PCR in 4 of 27 (14.8%) children and 8 of 96 (8.6%) adults.²⁷⁹ Ad was found in 5 of 306 (1.6%) blood samples from healthy donors. The Ad loads were higher in children (median of 1.7×10^5 Ad genomic DNA copies/mL; range of 4.2×10^2 to 1.1×10^{10} copies/mL) than adults (2.3×10^3 copies/mL; range 3×10^2 to 5.8×10^5 copies/mL). The highest load in the blood of the healthy control group was 1.7×10^3 copies/mL. In the transplant patients, symptoms suggesting disseminated Ad infection were seen in only two of six patients, both children, with high virus loads in the blood. One child with greater than 1×10^{10} copies/mL died.²⁷⁹ In a different study of SCT, a child died following a progressive increase in Ad DNA to about 10^{10} copies/mL in peripheral blood.⁴⁰³

The link between a high Ad load in the peripheral blood and fatal disseminated Ad disease was also established using qPCR in a retrospective analysis of 328 allogeneic SCT pediatric patients, 36 of which (11%) were positive for Ad.¹²¹ Seventeen patients had positive Ad cultures but no symptoms, 12 had symptoms but survived (10 had enteritis, 1 had hemorrhagic cystitis), and 7 had fatal disseminated Ad. In four of six fatal cases, a steep increase in Ad DNA in the serum was observed in the month preceding death, ranging from about 10^8 to 10^{12} copies/mL. However, some of the asymptomatic patients had Ad DNA loads in the serum of up to about 10^7 copies/mL, so quite high loads do not necessarily cause symptoms. In a prospective study of Ad DNA loads conducted by the same workers in pediatric transplants, Ad was found in the plasma of 12 of 48 patients (25%).¹²¹ Six patients developed disseminated Ad and three died; two of the three that were thought to die from adenoviremia had plasma loads of about 10^7 and 10^{11} copies/mL. The authors concluded that serum or plasma Ad DNA loads of greater than 10^6 copies/mL have an increased risk for fatal complications.¹²¹ In a retrospective qPCR study of 26 pediatric bone marrow transplant patients, 11 (42%) had Ad in the whole blood.⁷⁶¹ Of the children who had symptoms of Ad infection, Ad was isolated a mean of 17 days following transplant. Ad infection occurred more frequently in patients who had received T-cell depletion, and the two patients who died had very low absolute lymphocyte counts (less than $330/\mu\text{L}$) at the time when Ad was detected. These two patients developed an Ad DNA load of greater than 10^5 copies/mL in the blood.

One study in pediatric SCT patients also attempted to assess the link between Ad in the stool and blood with active disease. In 153 consecutive allogeneic transplantations involving 138 pediatric patients, Ad was detectable in serial stool specimens in all cases of Ad viremia during the posttransplant course. Peak virus levels of Ad in stool specimens above 1×10^6 copies per gram were associated with adenoviremia with a median of 11 days (range 0 to 192) between detection in the

stool and blood. Further, serial measurement of Ad levels in stool specimens permitted early diagnosis of impending invasive infection with a sensitivity and specificity of 100% and 83%, respectively.⁴³⁶

Several studies on Ad and transplantation have been conducted in adults. In an analysis of 2,889 adult bone marrow transplants using culture and histopathology methods to detect Ads, 85 (3%) of patients were positive.³⁹⁹ The mortality rate for Ad-positive patients was 26%. Perhaps the incidence of Ad would have been higher had PCR methods been used in this study. Consistent with this suggestion, in a prospective study of 76 adult SCT patients, 15 (19.7%) were positive for Ad by standard PCR assay.¹⁰⁰ Interestingly, the virus was found exclusively in patients whose T cells had been depleted, and 6 of the 15 patients (40%) developed Ad disease. Severe lymphopenia (less than 300 absolute lymphocyte count/ μL) when Ad was first detected was a major risk factor for development of Ad disease. Other key risks were positive Ad PCR in the blood and failure to reduce immunosuppression.

In another study of 62 adult T-cell-replete SCT recipients, serial blood samples were assessed retrospectively for detection of Ad by PCR.¹⁸⁴ Ad was detected in 21 (87.5%) of 24 patients with proven Ad disease, in 4 (21%) of 19 patients who shed Ad, and in 1 (10.5%) of 19 uninfected control patients. In those who progressed to proven Ad disease, viral loads were significantly higher (median maximum viral load of 6.3×10^6 copies/mL, range of 0 to 1.0×10^9 copies/mL), while all patients who shed Ad had symptoms compatible with Ad disease, suggesting possible infection. The minimal plasma viral load detected among patients with proven or possible infection was 10^3 copies/mL. Adenoviremia was detectable at a median of 19.5 days (range, 8 to 48 days) and 24 days (range, 9 to 41 days) before death for patients with proven and possible Ad disease, respectively.

Summarizing these data, weekly qPCRs to monitor the Ad DNA load and immune-reconstitution monitoring (CD3 counts) after HSCT are now widely used methods in many pediatric bone marrow transplantation units. Weekly monitoring is required because of the kinetics of Ad replication, which can be rapid. Such close monitoring can be useful in determining which patients are at risk for progressive infection (stable or rising DNA loads in patients with significant lymphopenia). Interventions have only been demonstrated prospectively to be effective in children, although suggestive data are emerging in adults.^{98,184,434,436} Reduction of immune suppression, reconstitution of Ad-specific immunity via adoptive transfer, and/or the use of antiviral therapy in such patients may prevent progressive disease. In some studies, there is anecdotal evidence that treatment with cidofovir and its lipid ester (CMX001) to suppress Ad may be beneficial (see section on antiviral drugs).^{328,434} Furthermore, Ad PCR-based monitoring can assess the impact of the intervention and determine if additional interventions are needed.⁴³⁴

Incidence data for adenoviral disease in solid-organ transplant recipients are even more limited than for SCT recipients. Ad infections appear most commonly in liver transplant recipients, pediatric transplant recipients, patients who receive antilymphocyte antibodies, and patients with donor-positive/recipient-negative Ad status.³²⁹ The problem of Ad hepatitis in 5 of 224 pediatric hepatic transplant recipients has been demonstrated.⁸⁶ The serotypes involved were common types, such as Ad1, Ad2, and Ad5. The clinical manifestations were

often the direct result of infection of the transplanted liver, and viral intranuclear inclusions were readily identified. The disease was acquired *de novo* or by reactivation of latent virus from an endogenous source. Forty-nine of 484 pediatric liver transplant recipients had an Ad isolated from either the liver, lung, or gastrointestinal tract. Twenty children had invasive Ad infection, which culminated in the death of nine patients.⁴⁷³ Some immunocompromised patients recovered from their Ad infections after discontinuation of immunosuppressive drugs. Enterocolitis occurs more commonly in small bowel transplant recipients and may mimic rejection.^{56,568} Adenoviral pneumonia is associated with graft loss, death, or progression to obliterative bronchiolitis for lung transplant recipients.⁷⁵ Ad genome detection in heart biopsy specimens has also been associated with worse outcomes among pediatric heart transplant patients (see Myocarditis section for more details).^{491,661}

Two studies have documented the natural history of asymptomatic adenoviremia in solid-organ transplant recipients. The incidence of Ad viremia was 6.5%, 6.7%, 8.3%, and 22.5% for adult kidney, heart, liver, and lung recipients, respectively.^{318,319} Few patients were symptomatic at the time that viremia was detected, viral loads in these patients were low, and none developed end-organ disease. There was no compromise of pulmonary function among the studied lung transplant recipients.³¹⁸ These data suggest that, unlike in stem cell transplant patients, monitoring patients for adenoviremia by PCR is not predictive of disease and is therefore not recommended.³²⁹

Another situation in which Ad is linked to immunosuppression is acquired immunodeficiency syndrome (AIDS). Twelve percent of patients with AIDS were reported to have species B Ads in their urine.^{148,311} Restriction endonuclease analyses of viral DNA of 24 urinary isolates have shown that all were related to Ad34 and Ad35. However, some of the AIDS urine isolates had the Ad7 hemagglutinin by serologic classification, suggesting recombination between the Ad35 and Ad7 species B (HA group I) agents. In addition to the HAs of Ad7 and Ad35, HAs from Ad3 and Ad11 have been found in other Ad35-like isolates from AIDS patients.³¹¹ In AIDS patients, the seroprevalence of Ad5 compared to Ad35 was 60% versus 7% in the Netherlands and 90% versus 20% in Sub-Saharan Africa.³⁸⁵ Occasionally, Ad35 has caused fatalities from pneumonia or hepatitis, as observed in three pediatric patients.³⁹⁴

Ads were observed by EM in colonic tissue of 5 of 67 (7.5%) and 30 of 377 (8.0%) homosexual men infected with human immunodeficiency virus type 1 (HIV-1) and studied because of persistent diarrhea.⁷⁰⁸ However, it is not clear whether species D Ads are associated with the chronic diarrhea that is common in these immunocompromised patients. The tissue biopsy samples had foci of mucosal necrosis, chronic inflammatory cells, and amphophilic nuclear inclusions observed by light microscopy. Thus, Ads, primarily newer isolates of species D, are present in the colonic lesions of some immunocompromised patients and may cause diarrhea but do not appear to be the etiology of the large number of intestinal dysfunctions that affect AIDS patients.^{285,331}

Persistence and Latency

Ads were discovered because of their propensity for persistence in adenoidal tissue.² These and other observations suggest that Ads may be able to establish long-term low-level persistent or perhaps even latent infections. We use the term *latent* to

imply that, as is the case with herpesviruses, the Ad genome is maintained in the cell in an unintegrated episomal state, and that few if any Ad genes are expressed. Little is known about the mechanism of persistence or latency for Ads in humans or animals (reviewed by^{466,787}).

In earlier work, Ad DNA was detected in tonsils²⁴⁸ and adult human lymphocytes.^{2,307} An Epstein-Barr–positive lymphocyte line and Ad-infected tissue culture cells have also documented persistence of Ad infection.^{15,114,203,204,401,663} In one study in primary peripheral blood mononuclear cells, unstimulated lymphocytes were mostly refractory to Ad productive infection, but replication occurred, especially with Ad11p and Ad35, in stimulated T lymphocytes.⁶³⁰ Not all cell lines support lytic infection, and latently infected cells apparently underwent phenotypic changes including decreased CAR expression that rendered the cells resistant to further infection by Ad5.⁸¹⁸ In another study, the majority of subjects analyzed had Ad in the gut tissue and gut-associated lymphocytes, as detected by PCR.⁸⁴ qPCR-based studies also suggest the possibility that Ads, at least those in species C, form latent infections in lymphocytes.^{224,452,465,466} In these studies, T cells appear more likely to have persistence than B cells with significant DNA-copy-per-cell variations (10 to greater than 2×10^6).^{224,225} Persistence has been most clearly demonstrated for species C Ad. The fraction of children with Ad DNA increased from about 60% at age 2 to higher at age 4 and then declined. Stimulation of DNA-positive cells with phorbol myristate acetate and ionomycin resulted in productive replication in 85% of the samples, suggesting the latent infection may be activated in life.²²⁵

Persistent or latent Ads could explain the clinical illnesses observed in immunocompromised hosts following tissue transplantation. One recent study after allogeneic stem cell transplantation proposed that the Ad complications seen were due to reactivation of persistent Ad in the patient rather than *de novo* infection.⁷⁵¹

The mechanism that maintains lymphoid cells in humans and in cell culture in an Ad latently infected state is unknown and is of considerable interest. All Ad promoters contain binding sites for transcription factors, and the delayed early promoters (E1B, E2, B3, E4) are transactivated by the E1A proteins. However, the E3 promoter is unique in that it contains two binding sites for NF- κ B, a transcription factor that functions to activate genes involved in inflammation and immunity.⁷⁸³ The E3 promoter is activated through these NF- κ B sites in an E1A-independent manner by TNF and other activators of NF- κ B.^{153,452} The E3 proteins protect Ad-infected cultured cells from destruction by CTL and the death ligands TNF, Fas ligand, and TRAIL, and cultured T and B lymphocytes are protected by the E3 RID protein from Fas ligand-induced apoptosis⁴⁶⁵ (see Fig. 56.3 and the section Function of Adenovirus E3 Proteins). Therefore, the E3 proteins may prevent the immune system from eliminating the infected lymphocytes.

Is There a Link Between Adenoviruses and Human Cancer?

Species A and to a lesser extent species B Ads can induce tumors in newborn Syrian hamsters, and Ad9 in species D can induce mammary tumors in rats (see Chapter 55), so the question arises as to whether Ads cause cancer in humans. The Ad E1A and E1B region sequences are sufficient for transformation of rodent cells by various Ad serotypes, and when Ads induce

tumors in newborn hamsters, the E1A and E1B regions, and often other regions as well, are integrated into cellular DNA. These integrated genes are expressed as proteins that mediate the transformed state. In most studies addressing the Ad etiology of human cancer, no Ad macromolecules (DNA, RNA, or proteins) have been found that are suggestive of an Ad infection.^{247,248,386,470} One group of investigators found Ad nucleic acid in neurogenic tumors,³²³ but these results await confirmation by others.

Other researchers have considered the possibility that Ads may play a role in acute lymphoblastic leukemia (ALL).^{252,303,748} Epidemiology studies suggest a link between *in utero* infection with viruses and ALL,²⁴⁶ and it has been reported that approximately 5% of amniotic fluid samples from sonographically sound pregnancies contain Ad DNA as detected by PCR, suggesting that Ad infections *in utero* are fairly common.⁴⁷⁵ In one study in which DNA extracted from Guthrie cards was analyzed by PCR for species C Ad DNA (the PCR primers were targeted Ad2 hexon DNA), such DNA was detected in 13 of 49 neonatal blood spots from ALL patients but only in 3 of 47 controls.²⁵² However, this intriguing association was not confirmed in a follow-up study by the same group in an analysis of DNA from Guthrie cards from 243 children who developed ALL and 486 matched controls,³⁰³ nor was such an association found by another research group using PCR primers specific for hexon DNA from species A, C, and F.⁷⁴⁸

Therefore, at this point there is no clear evidence that Ads cause human cancer, given the assumption based on rodent models that human cancer cells would retain and express *e1a* and *e1b* genes. For unknown reasons, human cells are resistant to transformation by the genes in E1A and E1B, although there are exceptions (reviewed by⁷⁸⁴). However, it is important to emphasize that the studies discussed previously do not rule out a “hit and run” mechanism for Ad-induced cancer in humans in which the virus causes changes in cells that lead eventually to cancer but the viral genome is not retained by the cells. In fact, a hit-and-run mechanism of transformation has been reported in which *e1a* plus either *e4orf6* or *e4orf3* cause transformation of primary rat cells without retention of these Ad sequences, possibly by inducing mutations in cellular DNA.⁵¹⁷

DIAGNOSIS

Differential Diagnosis

Many Ad infections of the respiratory tract are difficult to distinguish from other respiratory viruses and even some bacterial infections. In children younger than 3 years of age, small discrete white spots of exudate can appear on the tonsils and are consistent with Ad infection. They have to be distinguished from streptococcal infections and the manifestations of the Epstein-Barr virus mononucleosis syndrome or even some cases of herpes stomatitis, which in older children or young adults might start as exudate on the faucial tonsils. The most characteristic manifestation of Ad infection is the conjunctivitis as part of the keratoconjunctivitis syndrome, which usually begins unilaterally, causes moderate enlargement of the preauricular lymph node, and may subsequently involve the contralateral eye. The Ad-induced upper respiratory syndromes or pneumonias are impossible to distinguish clinically from other viral infections of these organs and must employ laboratory

diagnosis for clarification of the etiologic agent. Hemorrhagic manifestations of the urinary tract can be caused by bacterial infections as well as by Ad infections. In patients immunosuppressed with cyclophosphamide for bone marrow transplantation, manifestations of hemorrhagic cystitis can be due to drug toxicity in the bladder soon after transplantation. However, the isolation of Ads later in the course as a cause of the cystitis was reported in 13% of cases.³⁸¹ Ad as a cause of hemorrhagic cystitis is more common in Japan than in the United States, for reasons that have not been explained.

Laboratory Diagnosis

Collection and Preparation of Specimens

Collection of specimens from affected sites early in the illness is necessary to optimize viral isolation and to detect Ad antigens or nucleic acid directly in clinical samples. The duration of excretion of Ads at the time of acute infection is about 1 to 3 days from the throat in adults with the common cold; 3 to 5 days from the nose, throat, stool, and eye from patients with pharyngoconjunctival fever; 2 weeks from eye cultures from EKC; 3 to 6 weeks from the throat or stool of children with respiratory or generalized illnesses; and 2 to 12 months or longer from urine, stool, throat, or organ biopsies of immunocompromised patients.²⁸⁴ However, after the acute period, Ads may be latent in some tissues, such as the tonsils, or may be reisolated intermittently from throat or stool cultures for periods of months to years after primary infection in some patients.^{205,290} Ads obtained from throat swabs, nasal washes, conjunctival swabs or scrapings, and anal swabs are generally stable agents and withstand freezing and storage at -70°C , if immediate inoculation is not possible. Because some of the urine may be toxic to the tissue culture lines employed, it is best to remove the input inoculum after 2 to 4 hours of incubation. This time allows the virus to be absorbed before the cultures are re-fed with fresh medium. When cultures of blood mononuclear cells are desired, heparinized blood is fractionated on Ficoll-Hypaque gradients, and the washed cells are cultured in RPMI medium with fetal calf serum.³⁶³ Portions of these cells should also be co-cultivated on such cells as HEK cells, which are susceptible to Ad infection.

A common method for identifying Ad in the clinical virology laboratory is cell culture. For respiratory infections, specimens include nasopharyngeal swabs, washings, or aspirates, bronchoalveolar lavage fluid, or bronchial washings. For ocular infections, a swab of the infected conjunctiva is used. The inoculum is often placed into tubes of cell monolayers that are rotated. Cell types that are highly permissive for all human Ads except Ad40 and Ad41 are human neonatal kidney cells (these are semipermanent cell lines at very low passage) and primary HEK cells. Highly permissive permanent human cell lines that are used are A549 (lung adenocarcinoma), HeLa (cervical carcinoma), KB (nasopharyngeal carcinoma), and HEP-2 (hepatocellular carcinoma). Fibroblast cell lines are less permissive for Ad than the aforementioned epithelial cells. The highly fastidious enteric Ads, Ad40 and Ad41, can be grown on HEK293 cells. The ability of Ad40 to grow on HEK293 cells is a function of the Ad E1B-55K protein.⁴⁶¹

In current practice in many clinical virology laboratories, Ad detection in epithelial cells has been greatly accelerated by centrifugation of viral specimens directly onto the tissue culture cells (HEP-2), using the shell vial technique. This approach has

yielded positive cultures in 1 to 2 days for most serotypes or in 3 days for ocular Ads.³⁸⁸ In a clinical setting, initial testing is often done to distinguish between multiple viruses (influenza A and B, parainfluenza virus types 1 to 3, respiratory syncytial virus, and Ad).^{33,170,325,679,778} Nasopharyngeal swab, nasopharyngeal aspirate, and nasopharyngeal wash specimens are collected. A modified shell vial technique is used that combines a mixture of mink lung cells (Mv1Lu) and human A549 cells³¹⁶ or a mixture of A549 and primary rhesus monkey kidney cells.¹⁸³ The A549 cell line is a good host for most human Ads. After growing for 1 to 2 days, the cells are tested with monoclonal antibodies to identify the virus; Ads are identified by antibody recognition of the group-reactive epitope on hexon. Ad detection is best after at least 2 days of culture.^{170,183}

Respiratory infection or ocular samples are sometimes assayed directly for Ad without culturing the virus. Similarly, Ad can be diagnosed rapidly from the urine of patients with suspected Ad hemorrhagic cystitis.⁴⁸ The epithelial cells in the sample are washed by centrifugation, pelleted, and spotted onto microscope slides. The cells are then examined by IF using antibodies specific to Ad and visualized in a fluorescent microscope. Only 50 to 100 cells are required for this procedure. The method is rapid but is only 50% as effective as cell culture.

A commercial enzyme-linked immunoassay kit that has been approved by the Food and Drug Administration (FDA), named Adenoclone (Meridian Biosciences, Inc.), can be used to detect Ad directly in respiratory ocular or stool specimens.^{236,782} The assay detects most if not all human Ad serotypes, takes about 1 hour, and can be performed in the doctor's office. However, a high concentration of virus is needed such as is found within 1 to 3 days of clinical onset. Therefore, the assay is less sensitive than cell culture or IF staining.³⁰⁸ Thus, negative results need to be confirmed by cell culture methods.

In most instances in the routine clinical virology laboratory, once a positive Ad diagnosis is made, further work is not conducted to identify the serotype. However, as more is being learned about the pathogenesis of particular Ad serotypes, and for research purposes, PCR and qPCR, as well as restriction enzyme digestion of viral DNA, have become highly developed.

Identification and Classification of Viral Isolates

VIRAL SEROLOGY

Agents growing in tissue culture and demonstrating typical Ad CPE can be further processed to identify the isolate definitively. The methods used traditionally have been serology but now include restriction enzyme digestion of viral DNA and especially PCR analysis. Serologic confirmation in Ad typing can be separated into two categories. The IF and CF tests, using tissue culture material as antigens and reference antibodies, measure group characteristics of the Ads and are therefore usually shared by all human isolates.^{149,308} The hemagglutination inhibition (HAI) and serum neutralization (SN) tests measure type-specific parameters that can distinguish members of each group.³⁶³ See reference⁷⁸⁷ for details.

VIRAL DNA

In recent years, analysis of Ad DNA has gained prominence for detection of Ad in clinical samples and for subgroup typing. Characterization of the viral DNA by both hybridization and restriction endonuclease digestion patterns has been used for clinical isolates (see³⁰⁸, ^{23,148,185,375}). Because of small differences

in the DNA from various isolates, multiple restriction enzymes are often needed for a definitive identification. Although these small DNA differences can make interpretation of results difficult, they do lead to identification of strains that are of interest in the general epidemiology and pathogenesis of Ad.

Currently, PCR assays are being used for diagnosis, typing, and quantitation of Ad infections in various tissue specimens and body fluids.^{3,10,32,121,175,177,216,250,408,558,737,759,774,795,796} One study used PCR to amplify a portion of the *hexon* gene from all 51 serotypes followed by restriction fragment length polymorphism analysis and DNA sequencing.⁶⁵⁶ This method was especially useful for diagnosis of serotypes in species D (Ad8, 19, 37) and E (Ad4) that cause the majority of EKC in Japan. Most of the reports describe standard PCR but with the reactions set up in a multiplex format in which mixtures of primers and probes are used so that multiple serotypes can be detected simultaneously. The primers and probes are slightly degenerate in sequence to take into account small differences in DNA sequences among the different serotypes. One approach that could detect all 56 serotypes as well as many genome variants of Ads 1, 3, 4, 5, 7, 11, 19, 40, and 41 was to conduct PCR using primers specific to the conserved region of the *hexon* gene followed by restriction enzyme digestion of the PCR amplification products.¹⁰ This PCR assay could detect Ad40 and Ad41 on sodium dodecylsulfate/ethylenediaminetetraacetic acid (EDTA)-pretreated paper strips that have been proposed as a method to collect, store, and transport inactivated Ad from stool.⁸²³ Other PCR-only multiplex assays have been used for species C³ and D⁴ Ads using fiber-specific primers. Multiplex assays based on hexon have been used for species B Ad.^{216,408,795} Other research groups have developed multiplex assays based on fiber that can detect serotypes in all species, A through F.^{177,558,796} One assay, termed *PCR adenovirus consensus*, uses two degenerate primers specific to the Ad VA-RNA gene to amplify DNA from 51 serotypes.⁷³⁷ The amplified DNA is hybridized to a biotin-conjugated probe and is detected with a streptavidin peroxidase conjugate. Positive samples can be diagnosed further using species-specific hexon-specific primers. The assay is available commercially (Argene). Multiplex assays that can detect Ads, rotaviruses, and Norwalk-like viruses in a single reaction have been described.^{534,598}

Some workers have employed qPCR to detect and quantitate Ad DNA sequences (reviewed by⁷⁷³). This method was used for Ad4 in clinical samples^{191,314} and is versatile enough to be used in field situations to diagnose Ad4-induced ARD in military recruits.¹⁹¹ Nested qPCR has been combined with an antigen ELISA for broad detection of Ads.⁴⁷² Two groups have developed multiplex qPCR methods with primers and probes specific to hexon that can detect all serotypes in species A, B, and C.^{121,250} Both these assays had a sensitivity of about 50 to 250 copies/mL of Ad DNA. In another study, 51 serotypes in species A to F could be detected in one PCR reaction using a consensus primer and probe specific to a conserved region of hexon, but low stringency conditions were necessary.²⁷⁹ In a series of studies that took advantage of the DNA sequence of the *hexon*¹⁷³ and *fiber* genes, Ebner et al¹⁷⁵ developed a stringent qPCR assay that can detect all Ad serotypes. The DNA sequence differences in the conserved regions of the *hexon* and *fiber* genes precluded the design of a single PCR specific to all serotypes with optimal specificity, so a two-reaction PCR assay was developed. One reaction

covered serotypes in species A, C, and F, and the other was specific to species B, D, and E.¹⁷⁵

Quantitative PCR assays can be used to assess the antiviral efficacy of antivirals in cell culture⁶⁸⁵ and are useful to predict progression to disseminated disease in pediatric and, to a lesser extent, adult SCT recipients.^{98,184,197,222,337,434,436,351,539} Lastly, such qPCR methods have been useful in predicting response to interventions among immunosuppressed patients treated for Ad infections.^{13,181,419,632} In such situations, a decrease in the viral load of greater than or equal to 1 log in the 7 to 10 days after the first dose was administered was predictive of a successful outcome.⁴¹⁹

Lastly, a range of molecular methods have been developed that allow simultaneous identification and typing of strains of Ad from clinical specimens.^{11,60,174,182,244,443,449,462,573,599} Such assays have been used to identify the prevalent strains of Ad and risk factors for disease in a number of populations. Given the ease of such systems, compared to traditional serologic methods, most labs have moved to using such molecular systems to type viruses. Such assays have also been advocated as a major component of contemporary Ad designation systems.¹⁷

These various PCR and qPCR assays have been used to diagnose and sometimes quantitate Ad in respiratory and ocular specimens and in the blood, serum, and peripheral blood cells from immunosuppressed patients. A number of commercial laboratories offer analysis of clinical specimens for 56 serotypes using PCR or qPCR or will sell kits for these analyses. Further, there are a number of multiplex systems, particularly focused on diagnosing respiratory and gastrointestinal viral infections, that are able to detect Ad as part of a panel of other viruses that cause a similar clinical syndrome.^{29,217,395,438}

Direct Microscopy of Clinical Specimens

EXFOLIATED CELLS

Rapid diagnosis by direct examination of the cytopathology of exfoliated cells has shown variable degrees of success; reports indicate that IF techniques detected only one-third of the nasopharyngeal secretions from which Ads subsequently grew in tissue culture²²³ or that IF is as sensitive as tissue culture growth.³⁰⁸

Nasopharyngeal secretions and swab specimens have been used for direct fluorescent antibody testing (DFA).³⁰⁸ DFA can be a rapid initial test for seven respiratory viruses (influenza A and B, parainfluenza virus types 1 to 3, respiratory syncytial virus, and Ad). Cells are pelleted, transferred to slides, fixed, and stained with monoclonal antibodies specific for the seven virus groups.^{652,697,816} This assay is often run in parallel to shell vial culture for improved sensitivity.

The IF technique has not been useful in early diagnosis of conjunctival Ad lesions but may be more useful in studies of exfoliated bladder cells from patients with acute hemorrhagic cystitis.⁴⁸ Latex agglutination tests for detecting enteric Ad proteins in stool are available. They depend on specific Ad antibody to agglutinate latex beads in the presence of Ad proteins. Although evaluation of their sensitivity and specificity has indicated that they are useful in diagnosing enteric Ad infection, they are less sensitive than culture, they may give positive results with nonenteric Ads, and a significant number of positive reactions of stool extract with the latex controls can invalidate the test. Development of latex agglutination tests using monoclonal antibodies has increased the use of this assay.²⁴⁰

Electron Microscopy

EM of clinical specimens has been used in special situations to identify viral agents rapidly and specifically. The discovery of the “noncultivable” enteric Ads was made by EM examinations of stool extracts.²⁰² The EM morphology of the Ads is unique. The Ads in stool are primarily the enteric Ads, types 40 and 41. The other usual method to detect Ad in stool is an enzyme-linked immunoassay such as Adenoclone. These fastidious enteric Ads can also be grown on HEK293 cells and characterized further. On specimens from other body sites, immune EM for rapid diagnosis of respiratory infections was successful in detecting 19 of 25 throat swabs from which Ads were grown.¹⁷⁸ Although less sensitive than tissue culture growth, the EM technique was rapid. However, such approaches are not generally used to diagnose Ad infection of the respiratory tract.

PREVENTION AND TREATMENT

Therapy

With the emerging appreciation that Ads are a serious problem in EKC and in immunocompromised patients, there is recent interest in developing anti-Ad drugs (reviewed in^{176,197,294,328,378,409,416,418,434,762}). A class of drugs known as acyclic nucleoside phosphonates is effective against many DNA viruses including Ad¹⁴⁶ (reviewed in^{144,312}). One member of this class, (S)-9-[3-hydroxy-2-(phosphonomethoxy)propyl] cytosine, known as cidofovir, has been studied extensively off label in Ad infections. Cidofovir is an analog of deoxycytosine monophosphate in which the ribose has been replaced with an acyclic moiety. Because cidofovir is already a monophosphate, it does not require a viral enzyme for its phosphorylation (e.g., thymidine kinase [TK], which is required to phosphorylate acyclovir), and cidofovir can be converted to the di- and triphosphate forms by cellular enzymes. These triphosphorylated acyclic nucleoside phosphonates in general have higher affinity for viral DNA polymerases than for cellular DNA polymerases, thereby providing specificity for virus-infected cells. They act as inhibitors of the viral DNA polymerase, the triphosphate is a substrate for the polymerase, and, acting through a variety of mechanisms, they function as a DNA synthesis chain terminator.^{144,312}

Cidofovir is a potent inhibitor of Ad replication in cell culture.^{378,502} Cidofovir-resistant Ad5 mutants have been isolated that have sequence changes in the Ad5 DNA polymerase near the nucleotide binding site, implying that the target of cidofovir is the Ad5 DNA polymerase.³⁷⁷ In one study, cidofovir inhibited replication in HEp-2 cells of serotypes from species A, B, D, E, and F.^{482,483} Cidofovir has shown some efficacy in the rabbit^{123,378,601,602,603} and cotton rat³⁵⁹ models of ocular models of Ad5 infection.

A large multicenter trial was initiated in the United States to evaluate cidofovir against Ad ocular infections in humans (discussed in³⁷⁸). Significant efficacy was observed, but the trial was discontinued because of a narrow efficacy/toxicity ratio. Two other clinical trials have been conducted for cidofovir treatment of EKC: no efficacy was seen in one trial using 0.2% cidofovir plus 1% cyclosporine,²⁸⁸ whereas in the other trial, 1% cidofovir plus 1% cyclosporine lowered the frequency of severe corneal opacities but caused local toxicity.²⁸⁹

Cidofovir was examined in a number of retrospective studies as well as in case reports, alone or sometimes

in combination with ribavirin (1- β -D-ribofuranosyl-1,2,4-triazole-3-carboxamide), to treat systemic Ad infections in immunosuppressed patients.^{378,382,409} However, there have not been controlled clinical trials for systemic use of these drugs to treat Ad, and the drugs have not been licensed for this use. In early studies, cidofovir showed some efficacy against Ad in immunosuppressed HSCT and bone marrow transplant patients.^{62,295,415,440,589} Cidofovir was effective against Ad-associated hemorrhagic cystitis in bone marrow transplant patients.^{193,271} With eight pediatric SCT patients, cidofovir seemed to provide long-term suppression of Ad without dose-limiting nephrotoxicity.²⁹⁵ In a study in which Ad was detected in 26 of 155 pediatric HSCT patients, ribavirin was used when Ad was first detected and cidofovir was used in patients with persistent viremia.³⁵⁴ The authors concluded that, although not curative, the antiviral therapy appeared to control the Ad infection. In a study in which 57 of 177 pediatric HSCT patients were diagnosed with Ad, with eight having disseminated disease, cidofovir treatment led to clinical symptom resolution in 56 patients.⁸⁰⁹ In a study in which 71 pediatric SCT transplants were monitored, there were eight cases of Ad infection, three of whom died, but cidofovir seemed to provide benefit.⁶⁶⁷ In a recent study, eight immuno-

suppressed patients (three HSCT recipients, two liver–small bowel transplant recipients, one liver transplant recipient, one recipient with severe combined immune deficiency, and one with a T-cell deficiency) with adenoviremia and invasive Ad disease were monitored by qPCR analysis to determine their response to cidofovir (5 mg/kg every week for 2 weeks, then every other week).⁴¹⁹ Five patients clearly responded virologically and clinically to cidofovir; the remaining three patients had stable viral replication and eventually died. Of note, there was a significant delay between onset of symptoms and institution of therapy in three fatal cases (median time to death, 18 days). A decrease in the viral load of greater than or equal to 1 log in the 7 to 10 days after the first dose was administered was predictive of a successful outcome.⁴¹⁹ Other groups have documented a similar correlation of poor early response to cidofovir and progression to fatal disease.^{13,515} In another study, seven pediatric HSCT developed high-risk Ad infections and were preemptively treated with intravenous cidofovir (1 mg/kg three times weekly for nine doses).¹³ High-risk Ad infections resolved in all seven patients without renal toxicity. Cytomegalovirus (CMV) viremia occurred in two of seven patients during or shortly after therapy with cidofovir, suggesting benefit of early antiviral therapy.

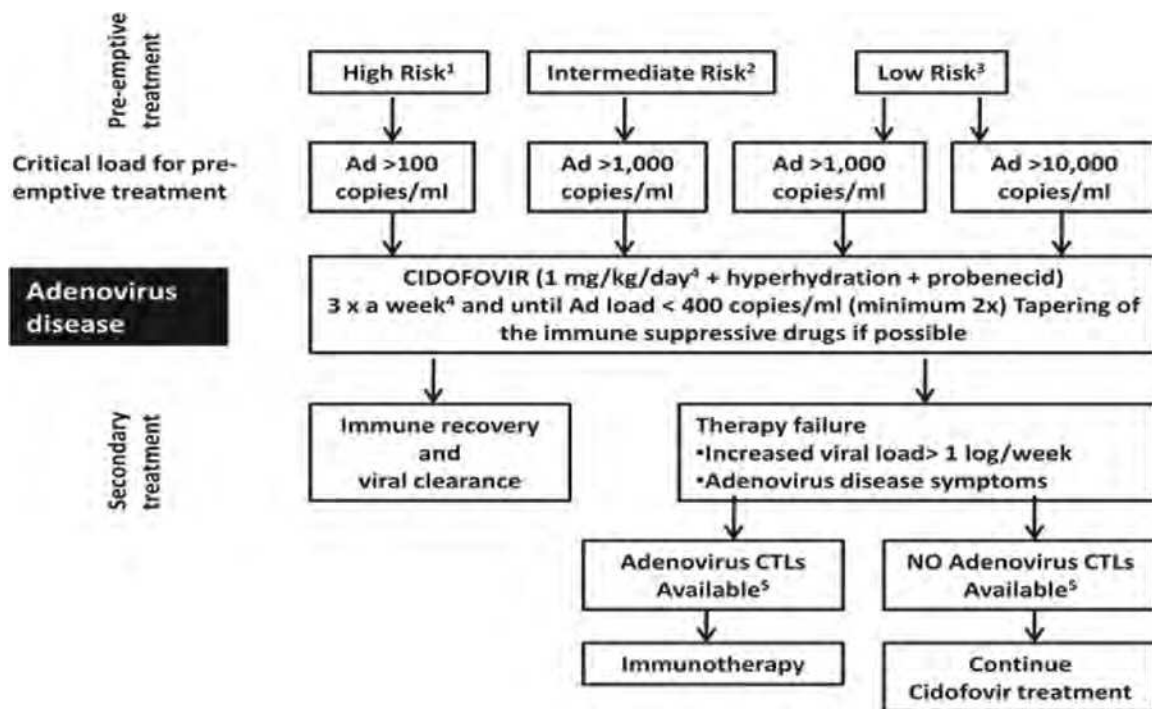

FIGURE 56.7. How Lindemans et al⁴³⁴ treat adenovirus (Ad) infections in pediatric hemopoietic stem cell transplant (HSCT) recipients.¹ Cord blood donor/T-cell–depleted graft recipient less than 1 month post-SCT AND/OR immune suppression: prednisone greater than or equal to 1 mg/kg/day and greater than or equal to one lymphocyte proliferation inhibitor (e.g., cyclosporine A).² Cord blood donor/T-cell–depleted graft recipient 1 to 4 months post-SCT AND/OR immune suppression: prednisone 0.5 to 1 mg/kg/day and greater than one lymphocyte proliferation inhibitor.³ Donor source other than cord blood or T-cell–depleted graft, or 4 or more months post-SCT for any donor source. Immune suppression maximum: one lymphocyte proliferation inhibitor and/or prednisone less than or equal to 0.5 mg/kg/day. CD3 monitoring when Ad greater than 100 genome copies/mL: CD3 less than 25/ μ L at detection OR less than 300/ μ L within 2 weeks; CD3 greater than 25/ μ L at detection AND greater than 300/ μ L within 2 weeks.⁴ An alternative is cidofovir 5 mg/kg intravenously weekly.⁵ For centers that have Ad-specific cytotoxic T lymphocytes (CTLs) readily available, CTLs are immediately initiated for all high-risk patients and for all patients with Ad symptoms before awaiting cidofovir effect. (Adapted from Lindemans CA, Leen AM, Boelens JJ. How I treat adenovirus in hematopoietic stem cell transplant recipients. *Blood* 2010;116:5476–5485.)

In case reports, cidofovir appeared to have anti-Ad activity in pediatric liver^{120,366} and renal¹⁷⁶⁰ transplants and in HSC,^{515,523} heart,⁵⁸³ and renal⁶⁹² transplants. Cidofovir seemed to resolve disseminated Ad in a pediatric liver transplant patient⁹¹ and Ad7 in a B-cell lymphoma adult patient with meningoencephalitis.²⁰⁰ Two adult renal transplant patients with disseminated Ad11 infection were successfully treated with cidofovir, intravenous immunoglobulin, and reduction in immunosuppression.⁶²⁰

In summary, these data and reports support the view that cidofovir can be employed against Ad infections with significant anti-Ad activity, but toxicity of cidofovir may limit its use. In fact, one group of authors have described a general approach in which they strictly monitor pediatric HSCT patients for Ad by qPCR and then for Ad-positive patients treat with cidofovir preemptively⁴³⁴ (Fig. 56.7); such approaches have not been studied in adult patients. Nevertheless, it still must be noted that a major concern with the systemic use of cidofovir is nephrotoxicity caused by accumulation of the drug in renal proximal tubules and cytopenias.^{144,145}

Because of the presence of the phosphate group on cidofovir, the drug shows poor oral bioavailability.^{144,312} However, a new series of ether lipid-ester prodrugs of cidofovir and other acyclic nucleoside phosphonates has been developed that increase oral absorption in the small intestine and facilitate cellular uptake

and metabolism.³¹² The lipid–nucleotide conjugate was designed to mimic lysophosphatidylcholine (LPC) and thus use the LPC uptake pathway in the small intestine. These prodrugs spontaneously insert into cellular membranes, the lipid moiety is hydrolyzed away by phospholipase C, and the compound is converted to the di- and triphosphate form by cellular enzymes. These di- and triphosphate forms tend to stay inside the cell because they are negatively charged and cannot easily pass through the plasma membrane. Alkoxyalkyl ester derivatives of cidofovir or (S)-9-(3-hydroxy-2-phosphonylmethoxypropyl) adenine [(S)-HPMPA] were reported to be 2 to 3 logs more effective than cidofovir or (S)-HPMPA in inhibiting five serotypes of Ad (Ad3, 5, 7, 8, 31) in cell culture.²⁶⁶ These compounds also have broad-spectrum activity against many double-stranded DNA viruses as compared with the unmodified nucleobases. Hexadecyloxypropyl-cidofovir (HDP-CDV; developed as CMX001 by Chimerix, Inc.) was the first of these compounds synthesized, it has been characterized extensively *in vitro* and in animal models, and it is being studied in clinical trials.³¹² As compared to cidofovir, CMX001 is not toxic to the kidney, although there is some gastrointestinal toxicity. In a Syrian hamster model for Ad5 infection, CMX001 was highly effective in eliminating Ad5 infection in the liver (Fig. 56.8), salivary gland, and pancreas when administered orally and daily beginning 1 day before or as long as 2 days

FIGURE 56.8. CMX001 decreases adenovirus type 5 (Ad5)-induced lesions in the liver. Syrian hamsters were immunosuppressed using cyclophosphamide, then infected intravenously with 1.9×10^{12} virus particles/kg of Ad5. Livers of hamsters sacrificed at day 6 were subjected to histopathologic and immunohistochemistry (IHC) evaluation. Animals infected with Ad5 and not treated with CMX001 exhibited extensive coagulation necrosis throughout the liver (**A**) and widespread replication of Ad5, demonstrated by staining for fiber (**B**). Treatment of Ad5-infected hamsters with CMX001 resulted in a significant reduction in hepatocellular injury (**C**) and greatly reduced IHC staining for fiber (**D**). The arrows indicate intranuclear inclusion bodies. The scale bars represent 200 μm for the larger pictures and 50 μm for the insets. N, necrosis. (From Toth K, Spencer JF, Dhar D, et al. Hexadecyloxypropyl-cidofovir, CMX001, prevents adenovirus-induced mortality in a permissive, immunosuppressed animal model. *Proc Natl Acad Sci U S A* 2008;105:7293–7297. Copyright 2007 National Academy of Sciences U.S.A.)

FIGURE 56.9. Plasma adenovirus (Ad) levels prior to (day +132 posttransplant) and during (day +133) treatment with CMX001.

Ad was first detected day +89 posttransplant, with a continued rise in Ad load despite administration of intravenous cidofovir days +92 to +132 posttransplant and intravenous immunoglobulin (IVIG) (day +129 posttransplant). Treatment with CMX001 was initiated on day +133 posttransplant at 2 mg/kg administered twice weekly increasing to 3 mg/kg after the sixth dose. After the virus became undetectable (less than 10^2 copies/mL) (day +159 posttransplant), administration of CMX001 continued at 3 mg/kg but the schedule was reduced to once weekly for maintenance. The inset shows the patient's dose normalized maximum plasma concentrations (C_{max} , ng/mL/dose [mg/kg]) and systemic exposure (AUC0-inf, h*ng/mL/dose [mg/kg]) of CMX001 after the 1st, 10th, and 20th doses (first three bars) in comparison to adult healthy volunteers (HVTs) administered a single dose (fourth bar). Arrows indicate timing of 1st, 10th, and 20th CMX001 doses. (From Paolino K, Sande J, Perez E, et al. Eradication of disseminated adenovirus infection in a pediatric hematopoietic stem cell transplantation recipient using the novel antiviral agent CMX001. *J Clin Virol* 2011;50:167–170. Copyright 2011, with permission from Elsevier.)

after an intravenous administration of approximately the lethal dose 50 of Ad5.⁷²⁷ CMX001 also displayed a remarkable ability to eradicate a disseminated Ad2 infection in a pediatric HSCT patient.⁵⁵⁰ In this patient, Ad DNA levels in the plasma increased to ca. 10^9 copies/mL despite cidofovir therapy, and the patient experienced renal deterioration caused by cidofovir; shortly following CMX001 administration, Ad DNA levels in the plasma decreased dramatically and the patient recovered (Fig. 56.9).⁵⁵⁰ In July 2011, Chimerix announced the beginning of the AdV HALT Trial, which is a randomized, placebo-controlled, multisite phase II clinical trial to evaluate the safety and efficacy of pretreatment with CMX001 for prevention of Ad disease following HSCT. In the trial, CMX001 will be administered orally to immunocompromised pediatric patients who have Ad infections but not evidence of disease. CMX001 (and similar lipid-linked prodrugs of acyclic nucleoside phosphonates) appears to hold great promise.

Ribavirin is a broad-spectrum antiviral drug with activity *in vitro* against a variety of viruses, especially RNA viruses, that is used to treat hepatitis C infections of the liver in combination with interferon- α and also respiratory tract infections in children by respiratory syncytial virus. The activity of ribavirin against

Ad replication in cell culture is controversial.⁴¹⁶ In general, ribavirin was considered to be modestly effective against only species C Ads,⁴⁸³ but in a more recent study ribavirin was reported to inhibit replication *in vitro* of clinical isolates of species A, B, and D as well as species C.⁴⁸² Mixed results have been obtained in about a dozen studies in the clinic with immunosuppressed patients (reviewed in^{378,409,416}). Successful use of ribavirin in combination with cidofovir has been reported.^{354,623} In a case series of four patients serially monitored with Ad DNA loads, ribavirin failed to have a meaningful clinical or virological impact, even though three of the patients clearly had species C Ads.⁴⁰²

Digoxin and furosemide are commercially available and show *in vitro* activity against Ad but have not been studied for the treatment of adenoviral infections.²⁶⁵ Likewise, ganciclovir has modest activity against Ad,⁴¹⁶ but there are limited data for the efficacy of ganciclovir in the treatment of adenoviral infections.³²⁸ Two studies revealed that patients who did not receive ganciclovir for prophylaxis were at greater risk of developing adenoviral infection and disease (odds ratio [OR], 3.4; 95% confidence interval [CI], 2.1 to 5.6).^{26,80}

A quite large number of other compounds have been identified that inhibit Ad replication in cell culture and in

animal models (reviewed in^{378,416}). Olomoucine II, that is, 6-(2-Hydroxybenzylamino)-2(*R*)-[[1-hydroxymethyl]propyl]amino]-9-isopropylpurine³⁰⁰; zalcitabine; alovudine; stavudine^{219,358,502,733}; halo-substituted stavudine phenyl phosphoramidate derivatives⁷³⁴; sanilbudine⁷³³; interferon- β ³⁹⁶; an antioestrogen peptide⁷³³; the sulfated sialyl lipid NMS03; the microbicide *N*-chlorotaurine^{378,416}; the cobalt chelate CTC-96 (Doxovir)^{378,416}; and aribidol⁶⁵⁴ have shown activity *in vitro* against Ad but have not been studied clinically for the treatment of Ad infections and are not undergoing active clinical development for this indication. Further, dehydroepiandrosterone, epiandrosterone, and some of their analogs inhibited Ad5 replication *in vitro*.⁶⁰⁵ Human α -defensins HNP1 and HD5 inhibit infection by a variety of Ad serotypes with a half-maximal inhibitory concentration (IC_{50}) of 3 to 4 μ M.⁶⁷² The defensins or their analogs could, therefore, be used for treatment of Ad infections. Likewise, the soy isoflavone, genistein, inhibits phosphorylation of p130^{CAS} and inhibits Ad late mRNA translation and therefore could also be investigated as an anti-Ad antiviral.^{422,792} Additionally, A3, which interferes with *de novo* pyrimidine biosynthesis, and GSK983, a novel tetrahydrocarbazole, have been demonstrated to have activity *in vitro* against Ad5.^{269,296}

An interesting and alternative approach to anti-Ad drugs is to exploit biological aspects of the host that the virus must employ in order to replicate efficiently. Ad5 enhances signaling through the Ras pathway; this activity is required for efficient replication inasmuch as pharmacologic inhibitors of MEK1/2 or ERK1/2 inhibited replication greater than 100-fold in cell culture.⁶²⁸ Perhaps such inhibitors could be used for Ad infections.

Ad-specific T cells are being explored as a therapy against Ad infection, with great promise (see the sections on Description of Key Antigens and Immune Responses).^{5,199,277,367,410,474,813}

Vaccine

As a result of the significant impact of Ad infection on the U.S. military, particularly new recruits in the 1960s, the U.S. Department of Defense and the National Institutes of Health (NIH) contracted with Wyeth Laboratories to develop and produce oral, live, enteric-coated vaccine tablets against Ad serotypes 4 and 7.⁴⁴⁶ These vaccines were administered to several million recruits over 25 years with excellent efficacy and safety. The manufacturer discontinued production of the vaccine in 1996, and Ad-associated acute respiratory illness returned to prevaccine levels.^{243,616} To address the re-emergence of Ad, the Department of Defense contracted with Barr Laboratories to develop and produce a new live, attenuated Ad4 and Ad7 vaccine.⁴⁴⁶ The new vaccine utilized the same Ad4 and Ad7 strains that were utilized in the original vaccine.⁴⁴⁶ The vaccine virus strains have been sequenced, annotated, and compared to prototype Ad4 and Ad7 strains. In doing so, it was determined that the Ad4 strains are recombinant: the inverted terminal repeat (ITR) of the Ad4 vaccine strain is identical to species C Ad, whereas the ITR of the prototype Ad4 strain is identical to species B1 Ad.⁵⁷⁵ Interestingly, neither the Ad4 nor the Ad7 vaccine strain appears to be attenuated based on bioinformatics analysis.⁵⁷⁵

In March 2011, the oral, enteric-coated vaccine was again approved for use in military populations 17 to 50 years of age, but it is not licensed for use in civilians. It is delivered as a single Ad4 and a single Ad7 tablet. The vaccine serotypes are packaged together in enteric capsules so that they bypass the respiratory epithelium and only replicate once they reach the intestine.¹³⁰

The enteric infection is typically asymptomatic, and it results in good neutralizing antibody responses. Circulating antibody is a reliable standard of immunity after administration of Ad vaccines. Hematuria, gastroenteritis, febrile gastroenteritis, gastritis, pneumonia, and hematochezia were recognized serious adverse events in vaccine recipients, but the incidence of any adverse effect was similar to those who received placebo. The vaccine efficacy was 99.3% (95% CI: 96.0% to 99.9%) for Ad4, while seroconversion was documented to be 94.5% (95% CI: 93.4% to 95.5%) and 93.8% (95% CI: 92.4% to 95.2%) for Ad4 and Ad7, respectively. Seroconversion is more likely among individuals who shed virus in the stool. No vaccine-type viruses were detected in throat swabs or blood of individuals who received the vaccine as part of a clinical study.⁴⁴⁶

The Ad vaccine has not been extended for use in children or civilians because of the risk of clinically symptomatic transmission between contacts. In a clinical trial of Ad4 vaccine in a small number of children, the infection spread to household contacts and resulted in a few clinically manifest illnesses.⁴⁹² Similar vaccine administration to adults commonly spread to sexual partners but infrequently to other adults housed together.⁶⁸¹ This transmissibility is likely the result of inadequate attenuation, as has been shown with sequencing data.⁵⁷⁵ Similarly, a small oral vaccine study in adults with Ad types 1, 2, and 5 resulted in virus shedding in the stool, some replication in the pharynx, and seroconversion, but no clinical illness.⁶²⁹

Adenoviruses as Vectors for Vaccination and Gene Therapy

As of 2011, ~415 gene therapy trials have been conducted or are ongoing with Ad vectors, accounting for ~24% of all clinical trials (<http://www.wiley.co.uk/genetherapy/clinical/>). Some trials have employed Ad vectors for gene therapy; for example, to deliver the correct version of a gene (typically as a complementary DNA [cDNA]) to a patient with a mutation in that gene, some vectors have been used as vaccines, but the vast majority of clinical trials with Ad vectors have been for cancer treatment. These various trials have indicated that Ad vectors are very well tolerated. Of further note regarding safety, millions of soldiers have been immunized safely with live Ad4 and Ad7 vaccines. The advantages of Ad vectors are multiple: the biology of the virus is well studied, they can be grown to produce stable and high-titer stocks, and they can infect both dividing and nondividing cells and cells and tissues of many different types (reviewed in^{76,77,257,725,803}). Ads rarely integrate into the host chromosome; thus, the vector DNA is maintained episomally.

Ads as vectors (Fig. 56.10) can be classified as replication defective (RD) or replication competent (RC). RD vectors serve to deliver the transgene into the target cell, whereas virus replication in the target cell is the intended mechanism of action for RC vectors.

RD Ad vectors have one or more essential viral genes deleted. With the “first generation” vectors these deletions encompass the essential E1 region (i.e., E1A and E1B), where the transgene is inserted, and the nonessential (in cultured cells) E3 region, which serves to increase cloning capacity (see Fig. 56.10B). These vectors can infect most cells and transcribe the inserted transgene. The constructs usually are made with plasmids into which the transgene is inserted, flanked by Ad genome packaging sequences (into virions), the origin of genome replication at the physical left end of the DNA (the

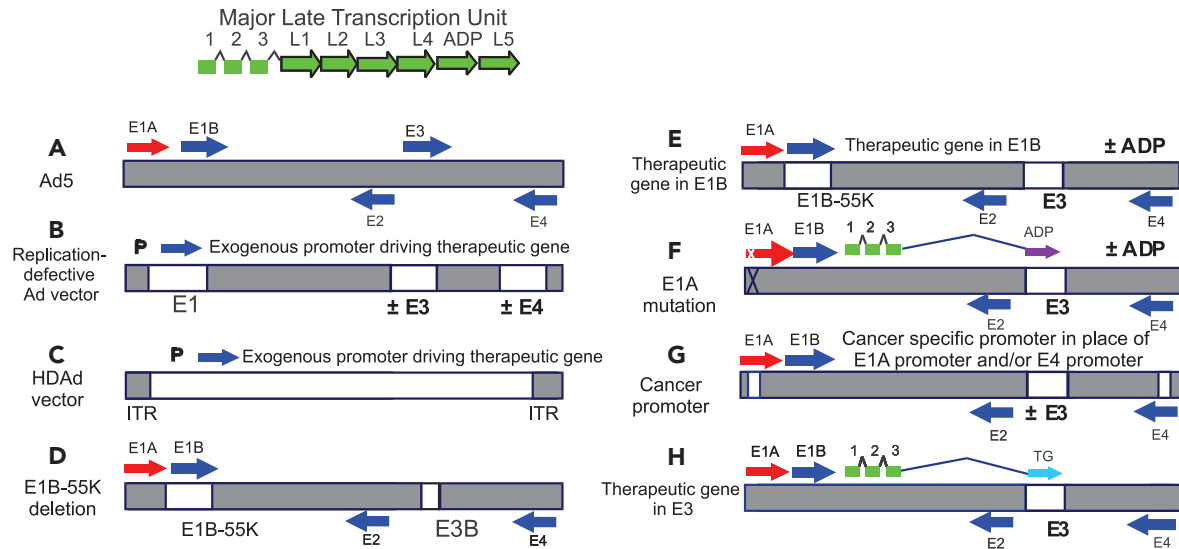

FIGURE 56.10. Schematic of the genome of adenovirus type 5 (Ad5) and Ad5-based vectors. **A:** Ad5. The horizontal bar indicates the duplex DNA genome of 36 kbp encoding ca. 35 genes. The arrows indicate transcription units. The “immediate early” E1A proteins derived from the E1A transcription unit (red arrow) induce expression of the “delayed early” proteins coded by the E1B, E2, E3, and E4 transcription units (blue arrows). Viral DNA begins to replicate at about 7 hours postinfection (p.i.), and then “late” proteins derived from the major late transcription unit (green arrows) are synthesized. The major late messenger RNAs (mRNAs) are formed by alternative splicing and polyadenylation of a large pre-mRNA initiated at the single major late promoter and extending to the right end of the genome. All late mRNAs have a tripartite leader (leaders 1, 2, and 3) at their 5' termini that facilitates translation. Beginning at 20 to 24 hours p.i., virions begin to assemble in the cell nucleus, and then after 2 to 3 days the cells begin to lyse and release virions, with lysis complete by about 5 to 6 days. Efficient cell lysis is mediated by adenovirus death protein (ADP). ADP is a late protein derived from the major late transcription unit. The vectors depicted are based on the Ad5 backbone. However, vectors based on serotypes other than Ad5 have also been developed. The reason for this is that Ad5 uses the coxsackie-adenovirus receptor (CAR) receptor, whereas some other serotypes use different receptors (e.g., CD46 and sialic acid as receptors), and sometimes this is an advantage. Also, pre-existing antibody levels in humans are more prevalent for Ad5 than for certain other serotypes. **B:** Replication-defective vectors. The E1A and E1B regions (transcription units) (i.e., the E1 region) are deleted and replaced with an expression cassette with an exogenous promoter driving expression of the therapeutic gene. In gene therapy vectors, this gene can be one to correct a genetic defect. In vaccine vectors, the gene is the antigen. In cancer gene therapy vectors, the gene (e.g., *p53*) induces cell death. Usually the E3 region is deleted. Deletion of E3 does not affect the growth of the vector because the E3 genes are not required for Ad growth in cell culture. Also, deletion of E3 allows for larger inserts into the E1 region because only up to 105% of the genome can be packaged into virions. E1-deleted vectors are defective for replication because the E1A proteins, and in some cells the E1B proteins, are required for virus growth. The vectors are propagated in cell lines such as 293 or PER.C6, which retain and express the E1A and E1B proteins. Although the E1A proteins are required for expression of other Ad genes, these vectors can be leaky and express other Ad genes in an E1A-independent manner, especially at long periods following infection and if high multiplicities of infection are used. In animal model studies, this leakiness has led to elimination of vector-transduced cells by cells of the immune system. For this reason, second-generation vectors also lack the E4 region. E4 regions are essential for Ad replication, including late gene expression, so deletions of E4 eliminate the leakiness. Some vectors also lack the E2 region. These E4- and E2-deleted vectors must be grown on cell lines that complement the E1, E4, and E2 deletions. **C:** Helper-dependent adenovirus vectors. These vectors lack all or most Ad genes but retain the *cis*-acting sequences such as the inverted terminal repeats (ITRs) at each end of the genome as well as the packaging sequence at the left end that are required for the genome to replicate and be packaged. These vectors are propagated in the presence of a helper Ad, which must be eliminated from the large-scale vector stocks. It is difficult to completely eliminate the vector. **D–H:** Replication-competent vectors. These vectors are mostly used for cancer gene therapy. The schematic in **D** depicts the vector ONYX-015, the first replication-competent (oncolytic) Ad vector to be described. It lacks the *E1B-55K* gene as well as the *rid* and *14.7k* genes in the E3B region. Because of the *E1B-55K* deletion, this vector grows better in cancer cells than in noncancerous cells. However, in many cancer cells, the vector does not grow as well as Ad5. Many other oncolytic Ad vectors have a similar design (e.g., H101), and as shown in **E**, by incorporating therapeutic genes into the *E1B-55K* gene deletion, and in some cases expressing the ADP from the E3 region (purple arrow). ADP enhances the spread of the vector from cell to cell. As shown in **F**, some vectors are targeted to cancer cells by virtue of deletions in the *e1a* gene that knock out binding of the E1A proteins to the pRB family of tumor suppressors, and also the p300/CBP proteins. Some vectors also express ADP from an alternatively spliced mRNA derived from the major late promoter. As shown in **G**, many vectors are targeted to cancer cells versus noncancerous cells by replacement of the E1A promoter/enhancer by a cancer-specific promoter. These vectors grow in cancer cells in which the promoter is active. Many different promoters have been used. In some vectors, the E4 promoter is replaced by a cancer-specific promoter. In **H**, a therapeutic foreign gene is expressed from the E3 region (TG, light blue arrow). The foreign gene can have anticancer properties (e.g., granulocyte-macrophage colony-stimulating factor [GM-CSF]); in some vaccine vectors, the foreign gene codes for an antigen.

ITR), as well as sites for recombination with the rest of the viral DNA to reconstitute adenovirions.^{58,291} These vectors are grown on cell lines that stably express the necessary E1A and E1B proteins. The best known such cell line is HEK293, which was generated by immortalizing primary human kidney cells with sheared Ad5 DNA, has the E1A and E1B regions integrated into cellular DNA,²³⁹ and is now known to have a neuronal lineage.⁶⁴⁹ Unfortunately, this cell line contains Ad DNA extending beyond the 3' end of the *E1* genes; at a very low frequency homologous recombination occurs between the Ad DNA in HEK293 cells and the DNA in E1-deleted vectors, thus generating contaminating RC Ads in RD vector stocks. Therefore, other complementing cell lines that do not carry any Ad sequences that overlap with the vector DNA were constructed, for example, PER.C6¹⁹² and N52.E6.⁶²²

The *in vivo* use of first-generation Ad vectors for gene replacement therapy is limited because of issues with immunity.^{76,77,631,633} Ads induce both humoral and cell-mediated immune responses^{137,505} (see Fig. 56.6) that result in toxicity, decrease the time that the transgene is expressed, and interfere with the effective readministration of the vector.⁵⁰⁴ The immunity seen with Ad vectors, which typically are applied in very high doses ($\sim 10^9$ to 10^{12} virus particles [vp] per kg), is probably different from what occurs in natural infections with much less virus.⁶⁵⁰ One problem with first-generation Ad vectors is the leakiness of expression of other Ad genes,⁶⁵⁸ especially those for the immunogenic virion proteins.⁸⁰⁰ Although E1A proteins are required to induce efficient transcription of other Ad genes, these genes can be expressed in an E1A-independent manner if high multiplicities of infection are used and if the infection is extended for several days. Thus, the first-generation

Ad vectors were altered further by deleting the E4 region and/or the E2 regions and then growing the vector on complementing cell lines that provide the E2 and/or E4 proteins.²³⁸ Such second-generation vectors have considerable promise as vaccine vectors.^{587,545}

A promising type of vector is the so-called helper-dependent Ad vectors (HDAds) (also referred to as gutless, gutted, or high capacity), which contain only the necessary *cis*-acting elements, namely, the two origins of DNA replication at each end of the genome and the packaging sequences from within the first 500 base pairs of the left-hand end (Fig. 56.10C)^{490,554} (reviewed in^{76,77,631}). These vectors, besides lacking any immunogenic Ad genes expressed by the vector, have a high cloning capacity (~ 37 kb), making it possible to insert whole loci, minigenes, and multiple transgenes. The HDAd vector genome is maintained as an episome in the nucleus in transduced cells; shortly after transduction, the Ad DNA packaging protein VIII is replaced by cellular histones and the genome assumes a transcriptionally active chromatin-like configuration.^{608,609} HDAd vectors cannot efficiently package genomes smaller than about 75% of the wild-type Ad genome, so “stuffer” DNA (eukaryotic DNA is superior to prokaryotic DNA) is used to make up for the required genome size.

HDAd vectors require a complementing helper Ad that provides all the required early and late gene products for the assembly of progeny virus. In a commonly employed method for HDAd production, the producing cell line for HDAd vectors conditionally expresses Cre recombinase, which, when activated, excises the loxP site–flanked packaging signal from the helper Ad's genome, thus ensuring preferential packaging of the HDAd DNA.^{260,553} (Fig. 56.11). Using this method and

FIGURE 56.11. Helper-dependent vector production and helper virus removal strategies. Generation of helper-dependent adenovirus (HDAd) vectors starts with the rescue of the HDAd DNA construct to its viral form. This is most commonly achieved by transfection of a complementing producer cell line (i.e., HEK293) with linear HDAd DNA followed by infection with a previously prepared helper virus stock (red virions). After cytopathic effect is evident, typically 36 to 48 hours postinfection, HDAd virions (green) are collected from the crude lysate and used along with helper virus supplementation (dashed gray arrows) for vector amplification. Using the Cre/loxP recombination-based approach, helper virus removal is achieved by using a Cre recombinase–expressing cell line capable of cutting out the helper genome packaging domain (Ψ) flanked by loxP sites, making it unpackageable. (From Segura MM, Alba R, Bosch A, et al. Advances in helper-dependent adenoviral vector research. *Curr Gene Ther* 2008;8:222–235, with permission.)

novel Cre-expressing 293 cells adapted for growth in suspension and a helper virus resistant to mutation, high yields of HDAd could be produced and helper virus contamination reduced to low levels (0.01% to ~1%).⁵⁴⁶ Another method for HDAd production has flt sites flanking the Ad packaging signal; excision of the packaging signal is mediated by FLP recombinase stably expressed in a complementing cell line.^{519,736}

For laboratory purposes, the HDAd is separated from the helper Ad based on their different buoyant densities in cesium chloride density gradients. Amplification of the HDAd vector and a gradual decrease in helper contamination requires multiple serial rounds of co-infection and purification of the HDAd away from the helper. For industrial or academic scale-up, infected cell lysates are concentrated by ultrafiltration and the virions are purified by anion exchange (typically) chromatography followed by polishing using size exclusion chromatography.^{161,549,631} Two phase I/II clinical trials have been conducted with HDAd vectors.^{684,779}

HDAd vectors are less toxic and transgene expression is longer than seen with first- or second-generation vectors.^{77,78,499,548,631,633,777} Transgene expression continued for more than 2 years in one study with HDAd vectors in baboons⁷⁶ and up to 964 days in another study in baboons when a balloon occlusion catheter was used to deliver the vector to the liver.⁷⁹

The innate immune response to Ad capsid proteins (see Fig. 56.6) begins within minutes of intravenous administration, peaks at about 6 hours, is lethal when a high dose is used (e.g., $>10^{13}$ virus particles/kg in large animal models^{489,531}), and varies with the human Ad vector species.²⁰ Ad vectors induce biphasic production of pro-inflammatory mediators, including the cytokines TNF- α , IL-6, IL-1 β , IFN- γ , and IL-12 and the chemokines MIP-2, IP-10, RANTES, MIP-1 α , MIP-1 β , and MCP-1.⁴⁹⁹ These molecules are produced mainly by dendritic cells and macrophages including Kupffer cells. This ability of the Ad capsid to induce the innate immune system rapidly was illustrated by the tragic death of a patient who, after intravenous treatment with a large dose of first-generation Ad gene therapy vector expressing ornithine transcarbamylase, had a massive elevation of inflammatory cytokines and disseminated intravascular coagulation resulting in multiple organ failure.^{580,581} This death is a singular event; one review states that 16,000 patients have been treated with Ad vectors of various types with a good safety profile.⁵⁶³

The infection events and the innate response to systemically administered Ad5-based vectors in rodents (mostly mice) are very complex and include multiple components (reviewed by⁶⁵⁰) (see Fig. 56.6). The vectors interact with red blood cells,^{89,522,634} platelets,⁶⁸⁶ neutrophils,¹²⁸ macrophages in the spleen,¹⁵⁸ and Kupffer cells in the liver (see later). Liver is the main organ infected by intravenously administered Ad5 and Ad5-based vectors, even though the Ad5 receptor CAR is in tight junctions in the liver and presumably unavailable to adenovirions.¹³² Interestingly, Ad delivered into mice systemically does not infect hepatocytes directly using CAR, but rather by binding to blood coagulation factors VII, IX, and X and protein C, all of which could mediate liver infection through heparin sulfate proteoglycans on hepatocytes.⁵⁵² More recent studies indicate that factor X is the most important factor in hepatocyte transduction (see Fig. 56.5).^{551,757,758} Factor X binds directly with high affinity to Ad5 trimeric hexon through hypervariable region 5^{7,9,352,757} and more importantly

hypervariable region 7.⁹ The Gla domain in factor X binds to those hypervariable regions in hexon, and a cluster of basic amino acids in the serine protease domain provides a “bridge” to heparin sulfate proteoglycans on hepatocytes^{127,757} through the sulfated side chains on the proteoglycans.⁷¹ Many but not all serotypes in species A, B, C, and D bind factor X; the serotypes that do not bind are in species D.⁷⁵⁷ Factor X-mediated liver transduction occurs independently of Kupffer cells,⁷ and it occurs not only in rodents but also in nonhuman primates (*Microcebus murinus*).⁸

In addition to blood coagulation factors, adenovirions interact with proteins (C4, C4BP) in the classical and alternative complement pathways, leading to complement activation, infiltration of leukocytes, platelet aggregation, and induction of pro-inflammatory chemokines and cytokines.^{119,339,371,637,638,639,640,713} Antibodies to Ad can opsonize the virions, resulting in Fc-mediated uptake and secretion of cytokines by activated macrophages.^{747,811} Further, platelet-activating factor generated from the reticuloendothelial system helps generate a syndrome resembling septic toxic shock.⁷⁹⁷

In Ad vector-transduced lymphoid cells, the pattern recognition receptors are sensors activated by virion components leading to activation of NF- κ B and interferon regulatory factors and transcription of type I interferon and cytokine and chemokine genes.⁶⁵⁰ Toll-like receptor 2 (TLR2) is activated by the vector capsid at the plasma membrane, and TLR9 senses the genome in endosomes.^{21,96,819} MyD88 (myeloid differentiation primary response gene 88) is required for signaling from all TLRs except TLR3.²⁶⁷ The sensing of intracellular Ad DNA is important in the innate response, and both TLR-dependent and TLR-independent pathways are involved. One study in murine plasmacytoid dendritic cells concluded that Ad DNA is recognized by TLR9 in endosomes.^{42,819} Other studies in murine conventional dendritic cells and primary macrophages found that Ad DNA is sensed through TLR-independent cytosolic components.^{194,526,527,819} In a study in both murine and human macrophages, internalized Ad DNA induced caspase-1 processing of pro-IL-1 β to IL-1 β via NLRP3/NALP3 and ASC; the latter are components of the innate cytosolic complex termed the *inflammasome*, which functions to detect “dangerous DNA”.⁴⁹⁸ This study⁴⁹⁸ did not reveal a role for TLR9, but another study in human primary macrophages concluded that TLR9 sensing of endosomal membranes containing Ad DNA led to activation of the NLRP3/NALP3 inflammasome and IL-1 β release; these results were not observed in murine macrophages.³⁵ Another study concluded, based on intravenous injection of RD Ad into mice as well as *in vitro* studies, that the vector, interacting with macrophage β 3 integrins via the RGD motif on the penton protein, and acting independently of TLR9 or the NLRP3/NALP3 inflammasome, triggers a predominantly IL-1 α -IL-1 receptor 1 inflammatory response (Fig. 56.12).^{158,507} In other studies in murine cells, the TLR/MyD88 pathway appears to cooperate independently but additively with the NOD2 (nucleotide-binding and oligomerization domain) signaling pathway in the innate response to HDAd vectors.⁶⁹⁵ The responses are speculated to occur in activated macrophages or hepatocytes and may involve sensing of vector DNA.⁶⁹⁵ Type I interferon induced by these signaling pathways in dendritic cells and macrophages activates NK cells to eliminate vector-transduced cells in the liver.^{820,821} In mice injected intramuscularly with HDAd vectors, multiple TLR/MyD88

FIGURE 56.12. Schematic diagram of adenovirus (Ad)-induced cytokine production in splenic macrophages as proposed by Di Paolo et al.¹⁵⁸ (1) Ad penton base interaction with integrin $\alpha v \beta 3$ promotes virus internalization into early endosomes. (2) Partial disassembly of the virion in the low-pH environment of the endosome allows release of the viral membrane lytic protein that disrupts the lipid bilayer. (3) Membrane disruption acts as a signal for increased transcription of pro-interleukin-1 α messenger RNA (pro-IL-1 α mRNA) as well as increased cytokine protein production. (4) Proteolytic cleavage of pro-IL-1 α by neutral proteases results in nuclear localization of the N-terminal (NTP) fragment and secretion of the mature IL-1 α protein. (5) Binding of IL-1 α to its receptor (IL-1R1) induces further signaling that produces a defined set of cytokines and chemokines. MCP-1, monocyte chemoattractant protein-1; mRNA, messenger RNA. (From Nemerow GR. A new link between virus cell entry and inflammation: adenovirus interaction with integrins induces specific proinflammatory responses. *Mol Ther* 2009;17:1490–1491. Copyright 2011, with permission from Elsevier.)

signaling pathways contribute to the development of vector-specific CD8+ T cells.⁵⁸⁸ Certain differences among these various reports will need further resolution.

After intravenous injection of an Ad vector, Kupffer cells take up ~90% of the vector, dying in the process, but playing a major role in the inflammatory response.^{431,788} Kupffer cells take up Ad vectors via scavenger receptors^{255,798}; the hypervariable regions of hexon appear to be involved in this vector uptake, independently of the binding of these regions to factor X.^{7,368} Although both Ad5 and Ad6 are closely related in species C, Ad6 has lower affinity for Kupffer cells (and hepatocytes) than Ad5, and swapping the Ad5 hexon hypervariable region of Ad5 with that of Ad6 reduced Kupffer cell uptake and liver infection.³⁶⁸ Serotypes in species B and D also have low affinity for Kupffer cells and liver infection.⁶⁴⁷ To increase the specificity of Ad delivery to select cell types (to avoid getting the vector into the Kupffer cells) and to address the difficulties of transducing some cells that lack CAR, some investigators have swapped the fiber of Ad5 to fiber of other serotypes.^{391,479,680,780}

The other aspect of antiviral immunity that limits the *in vivo* use of Ad5 as a gene therapy vector is the high prevalence of neutralizing antibodies against Ad5 in the population. To circumvent this obstacle, researchers have developed vectors based on other serotypes^{37,301} and nonhuman Ads.³¹ In one study, all seven hypervariable regions of the Ad5 hexon were exchanged with the corresponding regions of Ad48, a rare

serotype.⁵⁹¹ The vectors were mostly resistant to neutralizing antibodies against Ad5.

Other workers are developing chemical shielding techniques for Ad vectors. A common method is to covalently link the uncharged hydrophilic polymer polyethylene glycol (PEG) to virus particles via free amine groups on the capsid proteins.^{39,393,481,537,775,789} Although PEGylation can reduce infection/transduction efficiency, it can have significant benefits. PEGylation protects the virus against pre-existing neutralizing antibodies and Ad-specific cellular immunity; it reduces (a) the development of neutralizing antibodies,^{133,543} (b) innate immune responses^{134,481} including the activation of complement,^{139,713} (c) uptake of vector by Kupffer cells,⁴⁸¹ and (d) binding of the vector to erythrocytes and platelets.²⁹⁷ The size of the PEG moiety attached to the virion is important. Large PEG moieties (e.g., of 20,000 [20K] molecular weight) detarget the liver in mice as compared to PEG molecules of ~5K.^{162,298,790} Interestingly, an oncolytic Ad conjugated with 20K PEG retained its ability to suppress tumor growth in mouse models, and with reduced liver transduction.¹⁶²

Regarding the clinical trial use of first- or second-generation RD Ad vectors for gene therapy, among the first examples are delivery of the cystic fibrosis transmembrane transporter⁶⁰⁷ and dystrophin.⁵⁷⁶ Other examples are ornithine transcarbamylase; blood clotting factors VII, VIII, and IX; aquaporin; and bilirubin uridine 5'-diphospho (UDP) glucuronosyltransferase

(reviewed in⁸⁰³). Growth factors have been expressed in Ad vectors to promote the growth of new vessels to replace occluded ones.²⁴⁹ Ad vectors have been used to prevent the overgrowth of the arterial wall during the healing phase after angioplasty is performed to open blocked cardiac arteries.^{651,721} The goal of some ongoing trials is to transduce angiogenesis-promoting genes (vascular endothelial growth factor, fibroblast growth factor, hypoxia-induced factor α , platelet-derived growth factor) into vascular epithelia at sites of limited blood perfusion such as damaged heart muscle or the limbs of diabetic patients.

First- and second-generation Ad vectors are excellent for use as vaccines because they generate both a humoral and strong T-cell response to the transgene, tending to a T helper cell 1 (Th1) response (reviewed in⁴⁰⁴). The most extensive use of an Ad vector for vaccine purposes in humans has been in a series of clinical trials for immunization against HIV-1 (reviewed in^{81,165,214,242}).^{24,116,136,245,263,332,372,520,559,572} In these various trials, the vaccine was well tolerated, with repeat injections (intramuscular) as high as 10^{11} vp per injection. Among the first reports was the so-called STEP study, a phase IIb, double-blind, randomized, placebo-controlled, test-of-concept trial, using a mixture of three Ad5-based E1-deleted vectors expressing HIV-1 *gag*, *pol*, or *nef*, manufactured by Merck Research Laboratories.⁸¹ The trial was stopped early (in September 2007) because the vaccine did not reduce risk of HIV-1 acquisition or viral load after infection, and there appeared to be a higher number of HIV-1 infections in the vaccine group than in the placebo group.

This unexpected result raised concern in the HIV vaccination field.^{165,242} One hypothesis is that the Ad5 vector activated and expanded memory Ad5-specific CD4+ (and CD8+) T cells that became hosts for HIV-1 infection. Such cells could contact HIV-1, especially if they homed to mucosal surfaces.⁵¹ Arguing against this hypothesis, individuals without detectable Ad5-specific neutralizing antibodies at baseline nevertheless have Ad5-specific CD4+ (and CD8+) T cells, as do Ad5 seropositive individuals, and the CD4+ T cells expand similarly following vaccination with the vector.¹⁶⁵ Another hypothesis to explain the STEP trial results, supported by *in vitro* data,^{562,572} speculates that pre-existing Ad5 neutralizing antibodies can form complexes with the vaccine vector to promote infection of CD4+ T cells with HIV.¹⁶⁵ Whatever the explanation for the STEP trial results, the issues raised are of great interest in the use of Ad vectors for vaccine purposes and for gene therapy in general.

With Ad vectors to combat cancer, the vector nearly always has been injected directly into tumors, as reviewed in.⁸⁰³ Some vectors express immunomodulators to augment antitumor immunity (e.g., IFN- α , IFN- β , IFN- γ , IL-2, IL-7, IL-12, granulocyte-macrophage colony-stimulating factor [GM-CSF], CD40 ligand, and B7.1). Other vectors express tumor antigens (e.g., MART-1, gp100, L523s, pp65, α -fetoprotein, GA733-2, MUC-1, and prostate-specific antigen). Still other vectors express endostatin to inhibit tumor angiogenesis, a dominant-negative version of the epidermal growth factor receptor, somatotropin, the sodium iodide symporter, cell cycle inhibitors (pRB, p21, and p16), or pro-apoptotic proteins such as TNF- α , Melanoma differentiation-associated-7 (MDA-7)/IL-24, TRAIL, or p53.

Another approach is to have the vector express pro-drug-converting enzymes such as herpes simplex virus (HSV) TK, which converts ganciclovir to the monophosphate form; CD, which converts 5-fluorocytosine to 5-fluorouracil; or bacterial

nitroreductase, which converts the pro-drug CB1954 into a strong alkylating agent. One TK-expressing vector, named sitimagene caradenovec, has been evaluated in phase I/II and III clinical trials for operable primary high-grade malignant glioma.⁷⁴² The European Medicines Agency (EMA) concluded that the data did not provide sufficient evidence of clinical benefit and therefore they rejected marketing authorization.^{477,742} Other Ad TK-expressing vectors have been tested in clinical trials for hepatocellular carcinoma⁴²⁵ and prostate cancer.⁶⁶⁰

Another Ad5-based RD vector, named CTL-102, which expresses bacterial nitroreductase, was examined in a phase I/II clinical trial for localized prostate cancer.⁵⁵⁵ Prodrug CB1954 plus vector doses of 5×10^{10} to 1×10^{12} vp showed minimal toxicity and suggestive evidence for antitumor efficacy.

MDA-7/IL-24, a member of the IL-10 family, is a secreted cytokine that is considered to be a tumor suppressor that, when expressed intracellularly, can cause cell cycle arrest or death of a variety of cancer cells.¹⁵² In a phase I clinical trial conducted on patients with advanced melanomas and carcinomas, an RD Ad5-based vector expressing MDA-7/IL-24 was considered to be safe and to demonstrate a significant clinical response rate.^{152,171} Ad5-based vectors expressing interferon- β have been tested in clinical trials for mesothelioma⁶⁸³ and malignant glioma.¹¹²

The most clinical data, by far, has been obtained with two Ad5-based RD vectors, named Advexin and Gendicine, that express the transcription factor and tumor suppressor protein p53 from the E1 region of the vector (see Fig. 56.10B). Most cancers have nonfunctional mutations in the *p53* gene or are defective in the mechanisms that control p53 levels or p53-mediated functions. Expression of p53 causes death or inhibition of proliferation of vector-infected cells, most likely due to induction by p53 of genes involved in apoptosis, cell cycle arrest, and DNA repair and direct interaction of p53 with antiapoptotic proteins in the mitochondria.

More than a dozen clinical trials have been conducted with Advexin for cancers including head and neck squamous cell carcinoma (HNSCC), non-small cell lung cancer, colorectal cancer, hepatocellular carcinoma, glioma, prostate cancer, breast cancer, ovary cancer, and bladder cancer.^{324,513,610,635} Several phase I and II trials were conducted on patient groups with recurrent or refractory HNSCC, with Advexin intratumoral monotherapy, in perioperative or postoperative settings, and in various dosing regimes up to 2.5×10^{11} vp/dose, directly into tumors (reviewed in^{315,513}). These studies indicated that Advexin is safe and had minor durable antitumor activity. Two phase III trials were conducted, one that compared Advexin monotherapy to methotrexate in advanced recurrent HNSCC.^{509,513} Patients with a favorable p53 biomarker profile (no p53 or with wild-type p53) had an increase in survival of 7.2 months versus 2.7 months for patients with an unfavorable p53 profile (mutant p53 that could be a dominant-negative inhibitor of p53 expressed by Advexin) ($p < .0001$).⁵⁰⁹

Advexin is similar to Gendicine (reviewed by^{447,560,653}), which was approved in 2003 by the State Food and Drug Administration of China (SFDA) for the intratumoral treatment of HNSCC in combination with chemotherapy. Gendicine is the first gene therapy product to be approved anywhere for commercial use. Publications describing some of the HNSCC clinical trial results with Gendicine have appeared in the Chinese literature. One review describes that Gendicine is

quite safe (the side effects mentioned are similar to those with Advexin discussed earlier) and has significant anticancer activity including synergistic effects with radiotherapy and chemotherapy.⁵⁶⁰ More recent reviews state that more than 7,000 patients have been treated with Gendicine⁴⁴⁷ and describe additional clinical studies with Gendicine for a variety of cancers.^{315,447,653} Typically, 1×10^{12} vp have been administered intratumorally, with repeated administration.

Replication-competent Ad vectors are also being explored as drugs to treat cancer (reviewed in^{38,172,230,393,398,563,577,653,687,688,728,799,805}). Oncolytic Ad vectors kill cancer cells as part of the natural virus life cycle, so following replication the virions are released from the lysed tumor cell to infect other cells in the tumor. Because Ads rely in part on the host machinery for DNA replication, cells with a deregulated cell cycle (such as cancers) are more permissive than quiescent cells⁷³⁸ or normal human cells.²³¹ Nevertheless, many oncolytic Ad vectors incorporate additional features that restrict their replication, such as tumor-specific promoters driving expression of the E1A or E4 regions of Ad (see Fig. 56.10G). Vectors of this type have been evaluated in phase I clinical trials for prostate cancer, with encouraging results.^{154,596,668,804}

The first oncolytic Ad vector to be proposed for the treatment of cancer in humans was ONYX-015.⁶¹ This vector is actually the Ad5 E1B-55K deletion mutant *dl* 1520 (see Fig. 56.10D).³⁴ The E1B-55K protein binds to and neutralizes p53, a step postulated to be required for Ad to replicate. Because normal cells express p53, it was thought in theory that ONYX-015 should not replicate in these cells. Most cancer cells have defects in the p53 signal transduction pathway, so it was proposed that ONYX-015 should replicate in those cells. However, E1B-55K is a multifunctional protein and is required for Ad mRNA export from the nucleus. It now appears that the lack of E1B-55K-mediated export of Ad mRNA is the reason that ONYX-015 does not grow well in noncancerous cells.⁵³⁵ Cancer cells complement this defect in mRNA export, allowing the vector to replicate better in cancer cells than normal cells,⁵³⁵ although replication is reduced in many cancer cells compared to Ad5.

ONYX-015 has been evaluated in more than 15 phase I and II clinical trials for several different types of cancer,^{151,220,254,275,315,370,488,495,510,511,512,514,584,585,698,749} and more than 300 patients have been treated.⁴³² The initial focus of these trials was HNSCC.^{220,370,510,512} In these and later trials, up to 2×10^{11} vp were repeatedly administered intratumorally, either as monotherapy or in combination with chemotherapy. There was evidence of vector replication in tumors but not normal tissue. Tumor response rates were modest, and toxicity was limited and included injection site pain and transient fever.

Interesting results were obtained when ONYX-015 was evaluated in trials for refractory colorectal metastases to the liver. In a phase I/II clinical study of 35 metastatic colorectal cancer patients that had failed prior treatment with 5-fluorouracil/leucovorin,^{585,698} the vector was administered by hepatic artery infusion over multiple cycles in most patients in combination with 5-fluorouracil/leucovorin. No dose-limiting toxicities were observed, and the median survival of patients with stable disease or partial responses was 19 months versus 5 months in other patients. An acute enlargement of tumor masses was observed after infusion with vector followed by regression of these masses in 7 of the 11 patients.^{585,698} This tumor enlargement suggests that there was an inflammatory response to the vector and that

that response, perhaps a “cytokine storm,” may have contributed to the regression of the tumors.⁵⁸⁵

A number of other vectors similar to ONYX-015 that lack the *E1B-55K* gene are in evaluation in clinical trials. One such vector, named H101 (Oncorine), was evaluated in phase I, II, and III clinical trials in China.^{315,442,447,563,653,793,805,806} Significant antitumor responses were observed with relatively little toxicity, and no serious adverse events were reported. The H101 vector was approved in China in 2005 for treatment of HNSCC in combination with chemotherapy.³³⁸ This is the first oncolytic vector of any kind approved for commercial use, including viruses other than Ad. A report published in 2009 stated that more than 600 patients had received intratumoral injection with H101 in clinical trials.⁴²³

Another type of *E1B-55K*-deleted vector has reached clinical trials for prostate cancer (reviewed by²¹⁰). One vector, named Ad5-CD/TKrep, which expresses a CD-TK fusion protein from the deleted E1B region (see Fig. 56.10E), has proved to be safe and effective for the treatment of prostate cancer (injection into the prostate tumor, 10^{10} to 10^{12} vp per injection) when used in combination with radiation therapy and 5-fluorocytosine plus valganciclovir²¹¹ or 5-fluorocytosine plus ganciclovir.²⁰⁹ These compounds are converted by the CD-TK enzyme into metabolites that inhibit DNA synthesis in the infected and neighboring cells, and they sensitize cells to radiotherapy. A new version of this vector expresses an improved yeast CD-TK fusion protein from the E1B region and an Ad protein named adenovirus death protein (ADP) from the E3 region.⁴⁰ ADP, an 11.6-kD integral membrane glycoprotein, mediates the efficient lysis of cells at the culmination of infection, allowing Ad to be released from cells.^{717,718} High expression of ADP from oncolytic Ad vectors causes the vector to spread more rapidly from cell to cell^{163,164} and to spread in tumors.⁴⁰ Altogether, 79 prostate cancer patients have been treated with these vectors without serious side effects and with an improvement in survival relative to historical controls.²¹⁰

A commonly employed group of vectors has a deletion in *conserved region 2* (CR2) of the E1A protein, the region that binds to and inactivates members of the pRB family.^{215,280} This deletion permits efficient replication of the vector in cancer cells with a disrupted pRB pathway, and it reduces replication in normal cells. One such CR2 deletion, so-called delta24 (Δ or D24), has been built into a variety of *infectivity-enhanced* vectors.^{563,799} The issue addressed with such enhanced vectors is that many tumors (e.g., of the ovary and bladder) have low levels of CAR, the primary receptor for Ad5 and Ad5-based vectors. Therefore, researchers have incorporated an RGD-containing peptide into the HI loop of the Ad5 fiber knob; this allows the vector to infect cells via the $\alpha_v\beta$ integrins that are expressed abundantly on many cancer cells.^{391,696} Another approach is to construct vectors with a chimeric fiber consisting of the shaft of Ad5 fiber but the knob of Ad3 fiber.³⁹² The receptor for Ad3, desmoglein 2,⁷⁷⁰ appears to be expressed well on many cancer cells.⁷³² Several clinical trials and clinical studies have been conducted recently with the infectivity-enhanced and/or D24 vectors. The various vectors are named Ad5- Δ 24-RGD,³⁷⁶ Ad5/3-Cox2L-D24,⁵⁶⁴ and ICOVIR-7.⁵²⁸ In all these trials, the authors concluded that the vector was well tolerated and that evidence was seen for vector replication and anticancer activity.

Certain oncolytic Ad vectors as well as this class of infectivity-enhanced and/or D24 vectors have been “armed” by expression of GM-CSF from the E3 region of the vector.

GM-CSF is a secreted cytokine that stimulates growth and differentiation of myelomonocytic lineage cells, especially dendritic cells (DCs). One concept is that the GM-CSF will attract DC precursors to the vector-infected tumor and stimulate them to differentiate into DCs that will take up and process tumor antigens and migrate to local lymph nodes and induce antitumor responses. This enhanced antitumor response might be sufficient to overcome the generally immunosuppressive environment of tumors. Oncolytic vaccinia virus and herpesvirus vectors expressing GM-CSF have been evaluated in advanced clinical trials with excellent results.^{74,722} Clinical studies with oncolytic Ad vectors expressing GM-CSF are at an earlier stage^{94,95,104,384}; in general, the vectors appear to be well tolerated, with evidence of induction of antitumor immunity and of clinical benefit.

Stability and Inactivation of Adenoviruses

Being nonenveloped viruses with a well-organized capsid and a double-stranded DNA genome, Ads are expected to be stable. Ads survive for long periods in liquid or on surfaces in a desiccated state.²³⁷ Ads in simulated conjunctival samples can be shipped cross-country at ambient temperatures without losing titer.⁶⁰⁰ There are recent studies addressing methods to inactivate Ads. One study examined 21 germicides for their ability to inactivate Ad8.⁶¹⁷ Based on their results, these authors recommend disinfecting ophthalmologic equipment with 70% ethyl alcohol or ~5,000 parts per million chlorine. High-level disinfectants such as 0.55% *ortho*-phthalaldehyde, 2.4% or higher glutaraldehyde, or 0.2% peracetic acid may also be used, but equipment must be compatible and rinsed thoroughly. Environmental surfaces may be rinsed with ~1,900 parts per million chlorine, 65% ethanol with 0.63% quaternary ammonium compound, or 79% ethanol with 0.1% quaternary ammonium compound. Two disinfectants recommended by the Centers for Disease Control and Prevention and Association for Professionals in Infection Control and Epidemiology for elimination of Ad8 from ophthalmic instruments, 70% isopropyl alcohol and 3% hydrogen peroxide, were ineffective in this study.⁶¹⁷

A number of studies have employed ultraviolet light to inactivate Ad. One report described cross-linking Ad DNA with amotosalen-HCl and long-wavelength ultraviolet light,⁴³³ especially for enteric Ads that may contaminate water supplies. Enteric Ads can be inactivated, but they are more resistant to ultraviolet light than most other water-borne viruses.^{379,532,712} Ad40 can also be inactivated by ozone.⁷¹¹

There is very little information on the levels of Ads in the environment. It is well recognized, though, that Ads are stable in surface and ground water for a prolonged period of time.⁵⁹⁰ In one novel study, van Heerden et al⁷⁴⁰ used PCR, DNA sequencing of the PCR product, and real-time PCR to detect, type, and quantitate Ads in drinking water and river water in South Africa. Ads were detected in 5.5% (10 of 188) and 22.2% (10 of 45) of different samples of drinking and river water, respectively, at a level of less than one copy per liter of water. These are minimum numbers because the Ads were isolated from the water by adsorption onto glass wool, a process that is unlikely to be 100% efficient. Species D predominated in the drinking water and, perhaps not surprisingly, enteric Ads were found most frequently (70%) in the river water. In an earlier study by these authors using culture methods to detect Ad, Ad was detected in 30% (59/198) of drinking water samples, 16% (8/50) of dam water,

and 44% (22/50) of river water samples.⁷⁴¹ In swimming pool water that conformed to accepted specifications for treatment, Ad was found in 11% to 21% of samples.⁷³⁹

Several new techniques are currently under development or approved outside the United States to inactivate a wide range of pathogens in blood and blood products. Most of these systems appear to successfully inactivate Ad if present in the blood. The INTERCEPT Blood System utilizes amotosalen and 3 J/cm² long-wavelength ultraviolet light and has been shown to result in a 5-log reduction in titers in plasma.⁶⁶⁶ Another system using the frangible anchor linker effector (FRALE) compound S-303 also appeared to result in a 5-log reduction of Ad titers in whole blood.⁴⁹⁴ Other systems in development combine riboflavin (vitamin B₂) and long-wavelength ultraviolet light and appear to significantly reduce the titer of adenovirus present in blood.⁸⁵

PERSPECTIVES

Much has been learned from studying Ad replication and pathogenesis for the past ~60 years. Recently, we have gained a greater appreciation of the serious complications that arise from Ads in immunosuppressed patients. The future should see continued development of drugs as well as T-cell therapy to treat these infections. We have come to understand much about the innate and adaptive response to Ads in mice, and the challenge is to learn more about Ad-induced immunity in humans.

Another key challenge is to understand the molecular basis for Ad pathogenesis including differences that exist among the serotypes and species. No doubt further work on the molecular biology of Ads and the interaction of Ads with their receptor on cells in culture and especially in tissues will be instructive. Research on Ad vectors in animal models and in clinical trials will be necessary.

HDAd vectors will probably be employed more frequently in gene therapy clinical trials. HDAd and first- and second-generation vectors will continue to be developed as vaccines, in particular applying lessons learned from the Ad5-vector HIV-1 vaccine clinical trials.

Both RD (Gendicine) and RC (H101) vectors have been approved as drugs to treat cancer in China. Other vectors are making their way through trials elsewhere in the world, and it seems likely that one or more of these will reach commercialization. These vectors hold much promise, especially because they can be effective against tumors that are resistant to other treatments. Hopefully, information gleaned from the widespread use of Gendicine and H101 in China will facilitate the development of vectors elsewhere in the world. These and other studies hopefully will lead to an understanding of exactly which cells in which tissues are initially infected with the different serotypes, whether the lytic infection as described in cell culture studies occurs in these cells, how the virus spreads from cell to cell, and how the innate and adaptive immune response limits the infection.

Summary and Conclusions

INTRODUCTION AND HISTORY

Parvoviruses are small, nonenveloped viruses with a linear, single-strand DNA (ssDNA) genome of about 5,000 bases. The family *Parvoviridae* (Table 57.1) contains two subfamilies: *Parvovirinae* and *Densovirinae*. The latter infect invertebrates and will not be described in detail in this chapter. (The interested reader is referred to the latest report of the International Committee on Taxonomy of Viruses [234]). The *Parvovirinae* are divided into five genera: *Amdovirus*, *Bocavirus*, *Dependovirus*, *Erythrovirus*, and *Parvovirus*. The adeno-associated viruses (AAVs) among the dependoviruses require co-infection with a

helper virus for productive infection, whereas the others are all autonomous, although they require the host cell to go through S phase for viral DNA replication but do not induce cell division.²³⁴ The AAV helper virus is most commonly an adenovirus, or less frequently a herpesvirus.

In the first half of the 20th century, feline diseases characterized by enteritis, panleukopenia, and cerebellar ataxia were recognized as being of viral origin. In the late 1940s, a similar disease was noted in mink; in 1952, it was determined that those diseases were caused by similar small, DNA-containing viruses.^{399,431} Parvoviruses were isolated from rats (Kilham rat virus),²³³ and the H-1 virus isolated from human tumor tissue infected hamsters.⁴³⁰ Between 1960 and 1962, small particles were observed within Adenovirus preparations by electron microscopy, and the smaller virus (AAV) depended on co-infection of the cells with adenovirus for replication^{24,196,335} or on herpesviruses.⁶⁸ The human parvovirus B19 was identified in 1974 during screening of blood, and the name derives from the code for that sample. The B19 virus is clearly associated with transient aplastic crisis (TAC) in patients with sickle cell disease, as well as with the childhood fifth disease and with postinfection arthralgia. In 1978, a new virus of dogs (canine parvovirus [CPV]) caused myocarditis of neonatal puppies and enteritis in older dogs, and CPV proved to be a variant of the long-known feline panleukopenia virus (FPV).³⁴⁰ Over the years, many different parvoviruses have been isolated from animals and cell cultures, and by discovery of viral DNA using direct cloning and sequencing approaches.^{223,224,395} Many of the latter viruses grow poorly or not at all in cultured cells, or are not clearly associated with disease in animals.

BIOLOGY OF THE PARVOVIRUSES

The parvoviruses have small (~25 nm diameter) and structurally stable capsids that bind host cell receptors, small ssDNA genomes with few genes that control their interactions with their hosts, and they replicate only in dividing cells or in the presence of a helper virus. Parvoviruses are widespread, and the presence of integrated viral DNA in the genomes of many different vertebrates and invertebrates indicates that related viruses have likely been infecting animals for millions of years.^{41,222,226,267} The capsids transmit between hosts by routes that include fecal–oral, urine, and respiratory spread, and they are stable in the environment and are readily transmitted by contaminated fomites. The routes of entry into the body likely involve infection of dividing epithelial or lymphoid cells of the upper respiratory tract, oropharynx, or intestine. The viruses are relatively simple and do not induce the host cell to proliferate or manipulate the immune responses directly through viral gene products. Where

the mechanisms have been defined, the host and tissue tropisms are determined by the requirement for dividing cells of the autonomous parvoviruses, by host receptor binding, or by the cell-specific control of viral gene expression.

AAVs are cryptic viruses and are not clearly associated with any pathology. Natural hosts likely include most vertebrates, and the viruses are widespread and have been isolated from humans and other primates, horses, birds, cows, and sheep (see Table 57.1). Viral persistence is likely related to the ability of the DNA to integrate and establish a latent infection, and AAV sequences are found in many tissues.^{163,365} If AAV infects a healthy cell in culture in the absence of a helper virus, the viral genome does not replicate but may establish a persistent infection by chromosomal integration, and stable concatemers of AAV genomes in an extrachromosomal state are frequently found. In cell culture, the integrated AAV genome can be rescued by superinfection of the cells with a helper virus.¹⁹⁷ Extrachromosomal or integrated latency are likely functionally equivalent if the infected cell does not divide; however, in dividing cells, the nonreplicating extrachromosomal AAV DNA

would likely be diluted out. Stressing host cells allows some limited AAV replication. In cell culture, this can be achieved by exposure of the cell to genotoxic conditions that include ultraviolet irradiation, ionizing radiation, and cycloheximide.^{386,470}

There are complex two-way relationships between AAVs and their helper viruses. AAVs can inhibit the replication of adenovirus in a process that depends on the relative amounts of the two viruses and on the temporal relationship of the co-infection.^{81,82} Adenovirus inhibition likely results from AAV Rep protein inhibition of heterologous promoters, and that inhibition is also seen in co-infections of AAV and SV40, papillomavirus, and some herpesviruses.^{192,238,254,473}

TAXONOMY AND CLASSIFICATION

The Family *Parvoviridae* has unenveloped capsids of about 25 nm diameter with icosahedral symmetry composed of 60 copies of the capsid proteins. The nucleic acid is single-stranded linear DNA between 4 and 6 kb in length. The *Parvovirinae* infect vertebrates, and the *Densovirinae* infect insects and other invertebrates. The *Parvovirinae* are subdivided into five genera: *Amdovirus*, *Bocavirus*, *Dependovirus*, *Erythrovirus*, and *Parvovirus*. The *Densovirinae* are subdivided into four genera: *Brevidensovirus*, *Densovirus*, *Iteravirus*, and *Pefudenovirus* (see Table 57.1). Genera of the *Parvovirinae* are defined by their genomic and biological properties, whereas species are defined by their DNA sequence relatedness, biological host ranges, and/or capsid antigenicity.

There is significant variation in the details of the viral genomes and gene expression. Parvoviruses may package mostly negative-strand DNA, or both DNA strands in variable proportions, and the ssDNA genome has different hairpin structures at each end. There are generally two messenger RNA (mRNA) promoters and a single polyadenylation site near the 3' end. The erythroviruses are related to the B19 human parvovirus, and mature virions contain equivalent proportions of positive and negative sense ssDNA, approximately 5 kb in size. The DNA molecules contain inverted terminal repeats (ITRs), and there is a single transcriptional promoter as well as two polyadenylation signals. Amdoviruses are related to the Aleutian mink disease virus (AMDV), whereas the bocaviruses are related to bovine parvovirus and the canine minute virus and include many viruses of humans and other hosts. Dependovirus virions package equivalent numbers of positive- or negative-strand ssDNA genomes, with ITRs of approximately 145 nucleotides—of which the first nearly 125 nucleotides form a palindromic sequence.

Structure of Capsid and General Properties

The particle has a molecular weight (MW) of 5.5 to 6.2 × 10⁶ daltons. The buoyant density of the intact virion in cesium chloride (CsCl) is 1.39 to 1.42 g/cm³,⁴²⁴ and the sedimentation coefficient of the virion in neutral sucrose gradients is 110 to 122. The virions are resistant to inactivation, being largely stable for 60 minutes between pH 3 and 9 and at 56°C. The viruses can be inactivated by formalin, β-propiolactone, hydroxylamine, and oxidizing agents.

The capsids have T = 1 icosahedral structures assembled from 60 copies of between 2 and 4 forms of a single structural protein (virus protein [VP]: VP1, VP2, and VP3), which encapsidate the linear, ssDNA genome⁴³⁵ (Fig. 57.1). The atomic

(Courtesy of Agbandje-McKenna, University of Florida.)

structures of the capsids of many parvoviruses and AAVs share a similar structure^{5,229,402,435,447,469} (see Fig. 57.1). An eight-stranded, antiparallel β -barrel makes up one-third of the sequence of the major structural protein, and large loops connecting the strands of the β -barrel make up the capsid surface and determine host and tissue interactions, bind receptors, and form the epitopes recognized by antibodies. Antiparallel β -ribbons form a cylinder about the icosahedral fivefold axes and make a channel through the capsid in some of the viruses.^{118,150,229} N-terminal sequences of some VP2 molecules are externalized through that channel, allowing them to be cleaved to VP3, and DNA packaging occurs through that channel, leaving sequences from the 5' end of the genome outside the capsid.^{118,123,350} Other features of the capsid may include one large or three smaller spike-like protrusions surrounding the icosahedral threefold axes of symmetry, depressions about the fivefold axes, and dimple-like depressions at the icosahedral twofold axes^{87,435,469} (Fig. 57.1).

Conformation-dependent neutralizing epitopes are important targets of neutralizing antibodies on the exposed surface of CPV, minute virus of mice (MVM), AAV, and B19 capsids, and the raised regions around the threefold axes are favored binding sites.^{272,381,415,460,477} Linear epitopes include the exposed N-terminus of VP2 of parvovirus full capsids and the N-terminus of VP1 for the B19 parvovirus.^{113,141,257,307,381}

Functions of the Capsid Proteins

Most autonomous parvovirus and AAV capsids assemble from combinations of three overlapping proteins—MWs of 80,000 to 86,000 (VP1), 64,000 to 75,000 (VP2), and 60,000 to 62,000 (VP3)—although AMDV, B19, and simian parvovirus assemble from only VP1 and VP2.⁴²⁴ For the autonomous viruses, VP1 and VP2 are derived from alternatively spliced viral messages, and VP3 is generated in DNA-containing capsids by proteolytic cleavage of VP2. AAVs have three coat proteins: VP1 (~87,000), VP2 (~73,000), and VP3 (~62,000). The capsid proteins are not glycosylated but are variably phosphorylated.

The unique regions of VP1 of most or all parvoviruses contain a calcium-dependent phospholipase A₂ (PLA₂) enzymatic activity that is buried within the capsid but becomes exposed during cell entry.^{151,418,480} The VP1 unique sequence is exposed on the surface of B19 capsids, which may reflect a difference in the biology of that virus.¹⁴² The PLA₂ activities of the different viruses differ significantly, with the highest activity seen for porcine parvovirus (PPV).⁷¹ The N-terminus of VP1 contains basic

amino acid motifs that likely function as nuclear localization motifs during cell entry and capsid assembly.^{199,270,444,459}

Genome Structures and Organizations

All parvoviruses of vertebrates have similar genome structures, with terminal repeats required for DNA replication, non-structural protein genes on the left half of the genome (the 3' end of the –ve strand DNA), and capsid protein genes on the right half of the genome (Fig. 57.2). Smaller proteins are produced by alternative splicing of some viruses and include the NS2 protein in the viruses similar to MVM and the NP1 protein in the bocaviruses (see later discussion). The functions of the noncoding sequences between the capsid protein and the 5' terminal hairpin of the autonomous parvoviruses are less well understood; however, in the B19 viruses, there is a short open reading frame (ORF) encoding a protein (p11), and that region may also be involved in regulating the packaging of the

FIGURE 57.2. The genomes structures of different members of the *Parvoviridae*, showing genomes of three of the nine genera, the parvoviruses, the dependoviruses, and the erythroviruses, indicating the promoters and open reading frames of the major genes, non-structural and viral protein. The terminal hairpins are magnified approximately 20-fold relative to the intervening single-stranded sequences.

viral DNA.^{118,119} The smaller ORFs include the NS2 protein in several viruses, the 11KDa protein in the B19 human parvovirus, and a small ORF (SAT) that overlaps the VP1 and VP2 N-terminal sequence in an alternative reading frame.⁴⁸¹ Various alternative splice products have been identified for many viruses, although the predicted proteins produced have generally not been characterized.

Epidemiology and Antiviral Immunity

Many autonomous parvoviruses, including CPV, FPV, porcine parvovirus (PPV), and B19 human parvovirus, cause acute infections of their hosts that last for fewer than 10 days. The virus is cleared by the host immunity, and infectious virus is not subsequently shed.³³⁶ However, some parvoviruses show prolonged replication and persistence: Rodent parvoviruses may persist in the kidneys and be shed in the urine, whereas AMDV persists in mink and continues to replicate for the life of the animal.^{10,52,354} For B19 in humans, rare chronic persistent infections occur in individuals who are immunosuppressed, or who do not develop effective immunity.^{63,158,478}

The mechanisms of transmission among the parvoviruses vary and in many cases are not well defined. Carnivore parvoviruses such as CPV and FPV are spread by fecal–oral transmission.^{283,284,336} Some rodent parvoviruses also replicate in the intestine but may also be transmitted through urine after replication in the kidney.^{28,214} The human B19 virus replicates primarily in the bone marrow and is thought to be transmitted by respiratory routes.⁶¹

Cell-mediated immunity likely assists in recovery from infection; however, humoral immunity alone can protect animals against infection and is also important for recovery from infection, as immune immunoglobulin G (IgG) can arrest CPV replication in dogs and can terminate chronic human infections by the B19 parvovirus.^{61,63} Antibodies produced in older mink reduce titers of AMDV but do not eliminate the virus, thus a persistent infection continues.^{9,12,52}

Any role for antigenic variation in the epidemiology of the parvoviruses is not well understood. Viruses of different genera or species are distinguished by polyclonal sera; however, little antigenic variation is present within virus species, and any epidemiologic significance is not known, and the same changes often alter host range or other properties of the virus.^{85,287,310,333,338} For MVM, antigenic variants were readily selected with neutralizing monoclonal antibodies in tissue culture or in persistent infections of SCID mice,²⁷² although it is not known whether similar variation occurs in nature.

Genetic Variation and Evolution

These DNA viruses are replicated by host cell DNA polymerases; however, the single-stranded nature of the genome may make it susceptible to modification, and the mode of DNA replication may lead to significant sequence variation. The temporal rate of sequence variation is high ($>4 \times 10^{-4}$ variations per site per year) when measured over defined periods or during the growth of CPV through serial passage in tissue culture.^{25,276,393,394} MVM mutant strains grown persistently in mice or under monoclonal antibody selection showed variation at several sites owing to host or immune selection.^{272,275}

All parvoviruses are related through a distant common ancestor, and the sequences can be subdivided into several clades that show some correlations with the hosts of origin,²⁸⁰

although there are many variants. Parvovirus-related sequences are integrated into the genomes of several animals.^{41,222,226,267} Most were only partial or degenerate sequences, which would not generate infectious virus or recombine with infectious virus sequences. The finding of some syntenic sequences in related mammals shows that the integration occurred prior to the host evolutionary divergence, thus at least some of the integrations occurred millions of years ago.

Various different viruses have been seen to infect single host species. For example, within cows, three parvovirus sequences have been discovered by searching for nonhost DNAs.¹⁴ The several erythroviruses from primates (B19 and related human and simian parvoviruses) are most closely related to each other and to the chipmunk parvovirus; however, those are distinct from other human parvoviruses.^{109,198,391,475} Most viruses from rats, mice, and hamsters were found to be within the same clade along with CPV and the related viruses of carnivores and PPV,^{27,448} whereas AMDV appears to infect mink and grey foxes and is only distantly related to other parvoviruses of vertebrates. Recombination is quite common among the parvoviruses.^{280,392}

The human B19-like parvoviruses include three distinct clades that differ by 5% to 20% in sequence; within each clade, the viruses differ by less than 1% to 4%.^{72,162,198,391} Viruses from patients with persistent infections may show more variation than viruses from patients with acute infections. Many parvovirus strains have worldwide distributions, although some geographic clustering occurs.

The emergence of CPV illustrates specific features of the parvoviral evolution. The most recent common ancestor to all CPVs likely arose during the early 1970s.^{394,434} The CPV lineage included two major variants, and related viruses recovered from raccoons and other hosts suggested extensive exchange among the related hosts.¹⁶ Virus strains differed in various combinations of the two neutralizing epitopes, which were in many cases associated with capsid changes that influence receptor binding and host range.^{16,69,338,339}

Significant variation (of up to 16%) was seen in the genomes of AMDV isolates, most likely owing to the co-circulation and co-infection of animals with variant virus strains. Because that virus can form persistent infections with continuously circulating virus, mixed infections likely occur.³²² A hypervariable sequence within the capsid protein gene alters residues on the surface of the VP2 protein structure.^{51,291,321}

Infection Pathways

Parvoviruses bind to one or more cell surface receptors followed by endosomal trafficking within the cell within vesicles, release into the cytoplasm, and active or passive nuclear entry. There appear to be no substantial differences between the infections by the autonomous viruses and AAV (Fig. 57.3).

Capsid Structures and Cell Infection

The parvovirus capsid is a stable sphere of about 26 nm in diameter (see Fig. 57.1). Flexibility is required during infection to allow genome release and to expose protein structures from within the capsid. The VP1 unique region of 40 to 230 residues is not required for capsid formation or DNA packaging,^{439,444} and that sequence includes a basic amino acid motif, which likely acts as a nuclear localization sequence, and a PLA₂, which is active when released from the capsid.^{71,270,418,444,480} The

FIGURE 57.3. A general summary of the known or proposed infection pathways of viral capsids from the cell surface to the nucleus, as exemplified by the canine parvovirus binding to the transferrin receptor and being taken up by clathrin-mediated endocytosis. The later steps of the pathway, including sorting the endosomal system of the cell, and trafficking within the cytoplasm and into the nucleus may vary between viruses and are still not completely defined.

unique region of PPV showed approximately 100-fold higher PLA₂ activity than those of AAV2 or the human B19 parvovirus.⁷¹ The PLA₂ modification of the lipid components of the endosome may allow more efficient viral release.¹⁵¹

The viruses of vertebrates show various surface features, including raised regions around the threefold axis of symmetry, a depressed region spanning the twofold axis, and in many cases a pore at the fivefold axis of symmetry that runs through the capsid^{16,402,403,435} (see Fig. 57.1). The insect parvoviruses show a relatively smooth surface.^{228,402} The host ranges and tissue tropisms of CPV and FPV, and of MVM variants, are controlled by a small number of residues on the capsid surface.^{4,6,29,85,436,469}

Variability and flexibility in the capsid structure are important for viral infectivity and capsid functions—in particular, the externalization of VP1 and VP2 N-terminal sequences. Flexibility of surface loops was seen in CPV, FPV, and MVM capsids at different pH, and removal of Ca⁺⁺ or other cations from capsids altered their structures.^{114,401} For many parvoviruses and AAVs, the VP1 unique region can be exposed to the exterior after certain mild treatments, and that exposure was increased by changes of residues surrounding the fivefold axis of icosahedral symmetry.^{113,150,247,350,444}

Cell Receptor Binding

Various molecules mediate parvovirus cell binding and infection. A cellular receptor for parvovirus B19 is globoside or erythrocyte P antigen (glycosphingolipid tetrahexoseceramide), and people who genetically lack P antigen (p phenotype) are not susceptible to parvovirus B19 infection.^{57,59} The role of globoside binding is not well understood, and in some studies the capsids did not bind the globoside *in vitro*.²²⁷ Globoside is expressed on mature erythrocytes and erythroid precursors; in tissue culture, excess soluble globoside or anti-P monoclonal antibody can protect erythroid progenitors from infection. However, on other cells, it is uncertain whether the globoside is displayed on the cell surface or functions as a B19 receptor. The $\alpha 5 \beta 1$ integrin is a co-receptor for infection of erythroid progenitor cells.^{454,455}

Transferrin receptor type 1 (TfR) is used by CPV and FPV for cell infection, and receptor binding controls differences in the host ranges of those viruses.^{202,332} Capsids bind through contacts between the TfR apical domain and the capsid threefold spike.^{201,331} CPV and FPV also bind to sialic acids on some erythrocytes and host cells, although that binding does not mediate infection.^{34,37} MVM capsids bind sialic acids and

hemagglutinate mouse erythrocytes, and cell infection can be blocked by neuraminidase treatment of the cells prior to virus binding.¹¹⁶ Differences in affinity of binding result in differences in plaque size and pathogenicity in mice.^{6,273}

The AAVs can have broad cellular tropisms and infect various hosts. Infection may involve participation of more than one cell surface molecule. Receptors or co-receptors for AAV2 include heparan sulfate proteoglycan,^{231,421} human fibroblast growth factor receptor 1,³⁵⁹ and $\alpha V\beta 5$ integrin.⁴²⁰ The differences in tropisms of AAV serotypes allow matching receptors on desired target cells with specific forms of transducing virions. Retargeting AAV capsids to alternative receptors using a variety of approaches has allowed transduction of cells that are normally not susceptible.^{189,308,344,353,371,467}

Endocytosis and Endosomal Release

Parvoviruses require receptor-mediated endocytosis for cell infection. Capsids of CPV and MVM are taken up rapidly into cells by clathrin-mediated endocytosis, and the capsids become associated with clathrin-coated pits and vesicles during uptake.^{266,334} Infection is inhibited by treatment of cells with lysosomotropic agents, including ammonium chloride (NH₄Cl), chloroquine, or bafilomycin A1, indicating that low endosomal pH is required for infection.^{36,334,373,418} After uptake, capsids are detected in endosomes by antibody staining for several hours^{187,334,419,453}; by *in situ* hybridization, viral DNA was localized with the capsids in perinuclear compartments for at least several hours.⁴¹⁹ The infectious process appears to be slow, and CPV infection could be blocked by anticapsid antibodies injected into the cytoplasm of cells 4 or more hours after virus uptake.^{444,445}

Uptake and endocytosis of the AAV capsids follow similar pathways, and infection may require signaling after receptor binding.^{137,384} Infection can be affected by the activity of the proteasome system, as protease inhibitors can enhance the infection of AAV2 and AAV5 vectors.^{373,472} The capsids may be retained for long periods in the endosomal system before escaping into the cytoplasm and being transported to the nucleus.^{35,138,186}

The mechanisms of escape from endocytic vesicles into the cytosol are not fully understood, although wholesale lysis of the endosomal vesicles does not occur.^{334,418} The PLA₂ activity of the VP1 unique region is essential for infection, and that enhances the release of the capsids into the cytoplasm.^{71,142,151,171,418,480}

Transport Within the Cytoplasm

Capsids are likely released into the cytoplasm from a vesicle in a perinuclear location, and further processing and trafficking events in the cytoplasm likely occur before transport to the nucleus. Infection of cells by MVM is affected by the activity of the proteasome, because infection can be reduced by some proteasome inhibitors, including those of the chymotrypsin-like activity (N-tosyl-L-phenylalanine chloromethyl ketone and aclarubin) but not by inhibitors of the trypsin-like activity.³⁷³ Mechanisms involved in that activity are not clear; however, there is no clear evidence for ubiquitination of the capsid within the cells or direct proteolytic digestion of the capsids.³⁷⁴

Active mechanisms likely transport capsids to the vicinity of the nucleus. Transport to the perinuclear region and nuclear transport are blocked by treatment of cells with nocodazole to depolymerize microtubules and by injection into the cells of an antibody against the intermediate chain of dynein.^{417,419,445} By

electron microscopy, capsids were seen associated with tubulin and dynein structures *in vitro*, and viral capsids were also precipitated from infected cells along with intermediate chain of dynein.

Nuclear Transport

Nuclear transport is thought to involve the nuclear pore complex, although this has not been strictly proven, and injection of MVM capsids into the cytoplasm of *Xenopus* oocytes was shown to affect the structure of the nuclear envelope.¹⁰⁶ However, other studies suggest that parvovirus capsids pass through the nuclear pore intact.^{417,445} Nuclear entry may require modification of the capsid to expose nuclear localization sequences (NLS) in the VP1 unique region. A VP1 sequence can function for nuclear transport when conjugated to bovine serum albumin (BSA),⁴⁴³ which appears to be exposed on incoming virions, and antibodies to the VP1 unique region blocked infection when injected into cells before virus inoculation.⁴⁴⁴ MVM capsids have NLS in both VP1 and VP2, with two NLS mapped near the VP1 N-terminus (Fig. 57.4). A VP1 unique region that could mediate nuclear transport is required for efficient cell infection by MVM capsids, and infection was reduced significantly by mutations in the basic sequences in the VP1 N-terminal sequence.^{270,438} An internal basic sequence acts in a conformation-dependent manner when present in a trimer of VP2 proteins.^{269,270,372}

Viral DNA Release From the Capsid and Initiation of Replication

It is not clear how the viral DNA genome is released from the capsid for replication. Full capsids of MVM and CPV, and likely other viruses including AAV2, have 20 to 30 nucleotides of the 5' end of the viral genome exposed on the outside of the capsid, and the NS1 or Rep protein is covalently attached to the 5' end of that DNA in newly produced capsids.^{123,449} The 3' end of the viral DNA becomes exposed outside the capsid without capsid disintegration.^{113,114,444} In the nucleus, that extra-capsid DNA could be used to initiate DNA replication by the host cell DNA polymerase, where the DNA could be removed without disassembly of the stable capsid.

Autonomous Virus DNA Replication

The autonomous parvovirus genome is a linear ssDNA with terminal palindromes (Fig. 57.5), and many viruses have different palindromes at each end^{22,368} and primarily package the minus DNA strand.⁴²⁴ DNA replication has been most extensively studied for the rodent parvoviruses.^{23,425} Only two non-structural (NS) proteins are encoded by most parvoviruses. Replication depends on the DNA replication machinery of the cell and various cellular proteins, and the cell must pass through S phase.^{369,423,461}

The current model for autonomous rodent parvovirus DNA replication is shown in Figures 57.6 and 57.7.^{119,121} A hairpin formed by the palindrome at the 3' end of the viral genome serves as a primer for complementary strand synthesis (see step 1, Fig. 57.6). The elongating strand becomes covalently linked to the hairpin form of the 5' end of the template to form a linear duplex model covalently cross-linked at both ends by DNA hairpins (see step 2, Fig. 57.6). The hairpin formed at the right end is nicked on the newly synthesized strand by NS1

FIGURE 57.4. The nuclear transport of the parvoviral capsid proteins and capsids in the life cycle. Part (1) shows the processes include the cleavage of the VP2 N-terminal sequences containing a nuclear export sequence (NES) from the incoming particle and exposure of the N-terminal sequences of the VP1 protein containing a nuclear localization sequence (NLS). Part (2) shows association between the VP1 and phosphorylated VP2 results in translocation into the nucleus as dimers, where the particles assemble. Part (3) shows how the newly assembled particles are transported out of the nucleus and into the cytoplasm using the phosphorylated N-terminus of the VP2 protein as a NES. (Adapted from Valle N, Rioloobos L, Almendral JM. Synthesis, post-translational modification and trafficking of the parvovirus structural polypeptides. In: Kerr JR, Cotmore SF, Bloom ME, et al, eds. *Parvoviruses*. London: Hodder Arnold; 2006:291–304. Reproduced with permission of Taylor and Francis Books UK, and the authors.)

at a site 18 nucleotides downstream from the original 5' end, and NS1 is covalently linked to the 5' end formed by the nick (see step 3, Fig. 57.6). The 3' OH allows repair synthesis to fill the gap at the 3' end of the newly synthesized strand so that the right end of the intermediate is now a double-stranded form of the original 5' palindrome with NS1 covalently linked to the 5' end of the parental strand. The restored 5' end is 18 nucleotides longer than the 5' end of virion DNA (step 4, Fig. 57.6). The extended form of the right end palindromic sequence is denatured so that both strands can form hairpins (see step 5, Fig. 57.6), and the 3' OH at the end of the hairpin on the progeny strand primes DNA synthesis that extends through both strands of the linear duplex monomer so that a linear duplex dimeric structure is formed (see step 7, Fig. 57.6). The left end palindromic sequence is now in a linear double-stranded form at the center of the dimer intermediate (the dimer bridge), with

the GAA sequence from the bubble present in the left end palindrome hairpin on the left side of the dimer bridge and the GA sequence to the right (see Figs. 57.5 and 57.7), and those sequences determine the generation of virion DNA strands as outlined later.

Three sites in the dimeric intermediate are potentially susceptible to single-strand nicking by NS1: two in the covalently closed right end hairpins at each end of the intermediate and a third on the right side of the dimer bridge at GA/TC (nicked at TC; the GAA/TCC sequence on the left side of the dimer bridge is not a site for cleavage)¹²¹ (see Figs. 57.6 and 57.7). The resolution process is shown in Figure 57.7.¹²¹ Nicking at TC leaves NS1 covalently linked to the 5' side of the nick and a free 3' OH that can serve as a primer for DNA synthesis. The helicase activity of the bound NS1 unwinds the helix in the 3' to 5' direction, allowing the palindromic sequence of the dimer

cleaved by NS1 and converted to the extended duplex form, then the strands separated to provide a 3' OH to prime synthesis, which would displace a single strand containing both the plus and minus strands linked by the extended left end palindrome (Fig. 57.7). The original nick in the dimer bridge leaves NS1 covalently linked at the 5' end of the template strand for the last reaction and thus provides a stopping point for synthesis. The duplex molecule created is cross-linked at one end by the right palindrome and could go through multiple rounds of displacement synthesis to produce minus strands with the original flip orientation of the left palindrome for packaging into the virion, as seen in MVM.^{23,17} This model conforms to the observation that NS1 cannot cleave oriL when the left end palindrome is in the hairpin conformation but only when the left palindrome is in the extended duplex form of the dimer

FIGURE 57.6. The replication cycle of the autonomous parvovirus DNA, based on the rolling hairpin model for minute virus of mice (MVM). The viral genome is represented by a continuous line (shaded black for the original genome and different colors for the newly synthesized DNAs); the 3' end is indicated by an arrowhead. The letters L and R represent the left-end and right-end palindromic sequences, respectively. Upper- and lowercase represent the “flip” and “flop” versions of the sequences, which are inverted complements of each other. (From Cotmore SF, Tattersall P. Parvovirus DNA replication. In: *DNA Replication in Eukaryotic Cells*. New York: Cold Spring Laboratory Press, 1996:799–813, with permission of Cold Spring Harbor Laboratory Press and the authors.)

bridge in the RF. However, NS1 can nick oriR when the right end palindrome is hairpinned.

The genomic ssDNA is generated and packaged when capsids are present. The RF structures giving ssDNA production for encapsidation are undetermined but do not appear to be simple linear duplex monomers; they are likely complex NS1/DNA complexes that are associated with capsid structures.^{119,121}

NS1 is the major parvovirus regulatory protein and is a helicase, adenosine triphosphatase (ATPase), and site-specific nickase that binds to the sequence 5'ACCA3'.^{101,111,458} When NS1 nicks, it becomes covalently attached to the 5' side of the nick through residue Y210.^{26,123,317} This site in the protein is in a motif characteristic of proteins involved in rolling circle replication (RCR motif).²⁰⁶ NS1 cleaves at a site within the extended duplex form of oriL in the dimer bridge and at a site within the hairpinned form of the right end palindrome, but not the hairpinned form of the left terminal palindrome (see Figs. 57.5–57.7). NS1 can presumably cleave the extended duplex form of oriR that would exist in a concatemer bridge with a tail-to-tail junction of monomeric units. Whether the type of asymmetry observed in the cleavage of the oriL bridge would occur has not been reported. The left end palindrome contains a short sequence that is not complementary; when extended in the dimer bridge, there is a 5'GA/TC to the right of the axis of symmetry and a 5'GAA/CTT to the left. Cleavage only occurs at the 5'GA/TC site, owing at least in part to a requirement for a cellular protein (parvovirus initiation factor [PIF]) to be part of the cleavage reaction.^{97,99} The sequence of the nucleotides in the “bubble” mismatch is not critical; however, the number of nucleotides is, owing to the need for interaction between NS1 and the cellular protein so that adenosine triphosphate (ATP) hydrolysis can occur,

allowing the double helix to be unwound and NS1 cleavage of its single-stranded substrate. Both NS1 and PIF can bind to both sides of the dimer bridge, although only the dinucleotide bubble sequence allows formation of the necessary ternary complex (see Fig. 57.5). PIF is a cellular transcriptional factor of the KDWK motif family, which functions as a heterodimer with subunits of 96 and 79 kda.¹⁰⁰

Three sequences are required for NS1 cleavage of the covalently closed hairpinned form of oriR found in the dimer RF. An NS1 binding site is near the axis of symmetry in the right end palindrome and another just outboard of the nicking site, and NS1 binding to the two sites leads to looping of the double helix of the hairpin and positions NS1 relative to the nicking site to allow the helicase to expose the site and NS1 to cleave.^{112,120} A cellular protein, either HMG1 or 2,¹²⁰ acts in concert with NS1. HMG1/2 preferentially binds to bent DNA, heterocruciforms, and Holliday junctions, and likely assists NS1 in creating the bend in the double helical hairpin to allow oriR cleavage.

Two additional sequences near the right end of the MVM genome affect DNA replication. There is a 65-nucleotide repeat from 4760 to 4850; deletion of one copy of the repeat reduces replication by 100-fold.³⁸² There is also a so-called internal replication sequence from 4489 to 4695.⁶⁷ Deletion of this sequence reduces the extent of DNA replication by 5-fold. Whether these regions function as internal oris is unknown.

Additional cellular proteins are required for MVM DNA replication, including phosphokinase C (PKC), where PKC ϵ is required for NS1 to function in RCR,^{107,316,319} and PKC λ phosphorylates NS1 at T435 and S473 so that NS1 can function as a helicase.²⁵⁵ G1 phase cell extracts do not support MVM DNA replication *in vitro*; however, the addition of cyclin A to the G1 phase extract allows DNA replication.

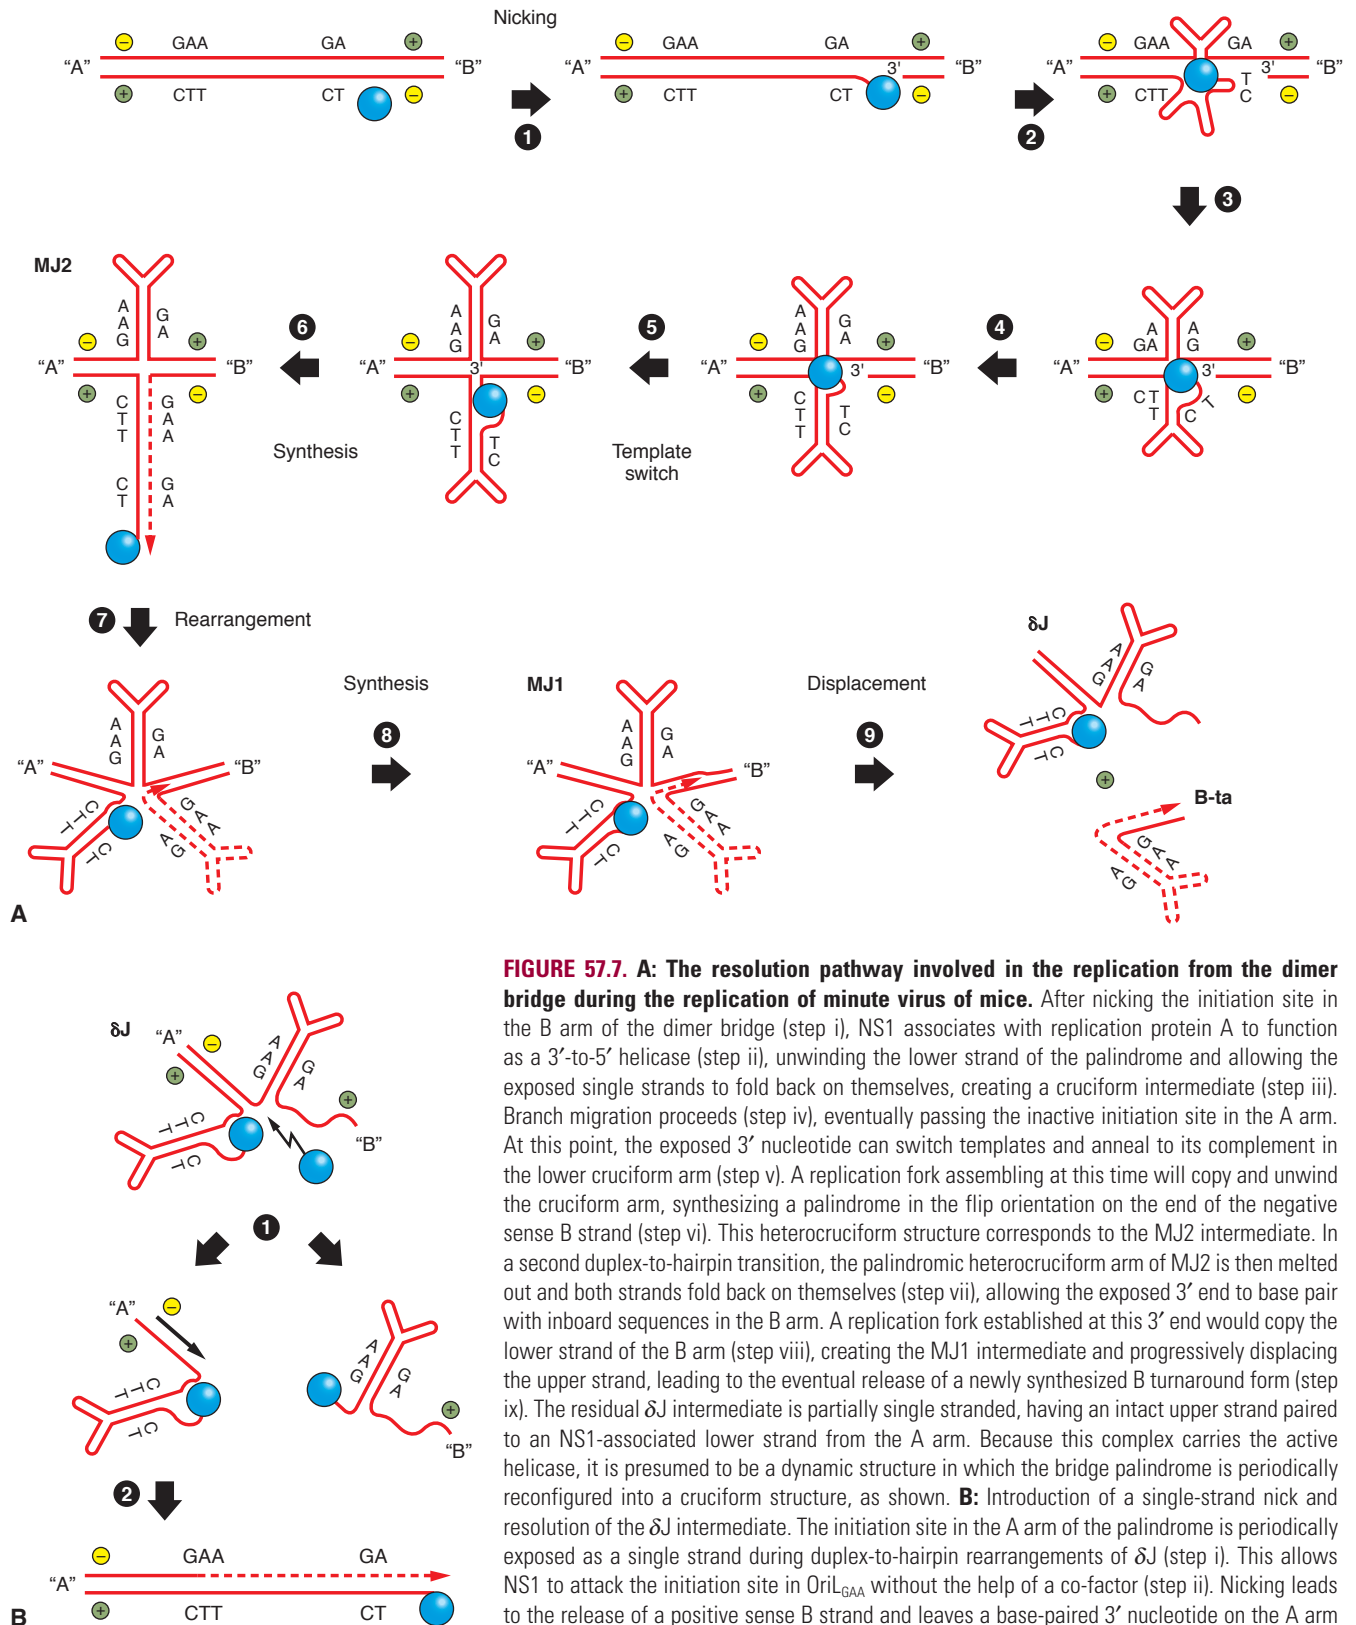

FIGURE 57.7. A: The resolution pathway involved in the replication from the dimer bridge during the replication of minute virus of mice. After nicking the initiation site in the B arm of the dimer bridge (step i), NS1 associates with replication protein A to function as a 3'-to-5' helicase (step ii), unwinding the lower strand of the palindrome and allowing the exposed single strands to fold back on themselves, creating a cruciform intermediate (step iii). Branch migration proceeds (step iv), eventually passing the inactive initiation site in the A arm. At this point, the exposed 3' nucleotide can switch templates and anneal to its complement in the lower cruciform arm (step v). A replication fork assembling at this time will copy and unwind the duplex arm in the flip orientation on the end of the negative sense B strand (step vi). This heterocruciform structure corresponds to the MJ2 intermediate. In a second duplex-to-hairpin transition, the palindromic heterocruciform arm of MJ2 is then melted out and both strands fold back on themselves (step vii), allowing the exposed 3' end to base pair with inboard sequences in the B arm. A replication fork established at this 3' end would copy the lower strand of the B arm (step viii), creating the MJ1 intermediate and progressively displacing the upper strand, leading to the eventual release of a newly synthesized B turnaround form (step ix). The residual δJ intermediate is partially single stranded, having an intact upper strand paired to an NS1-associated lower strand from the A arm. Because this complex carries the active helicase, it is presumed to be a dynamic structure in which the bridge palindrome is periodically reconfigured into a cruciform structure, as shown. **B:** Introduction of a single-strand nick and resolution of the δJ intermediate. The initiation site in the A arm of the palindrome is periodically exposed as a single strand during duplex-to-hairpin rearrangements of δJ (step i). This allows NS1 to attack the initiation site in Ori_LGAA without the help of a co-factor (step ii). Nicking leads to the release of a positive sense B strand and leaves a base-paired 3' nucleotide on the A arm (step iii) to prime assembly of a fork that will copy the hairpin, creating an extended form of the A arm (step iv). (Adapted from Cotmore SF, Tattersall P. Resolution of parvovirus dimer junctions proceeds through a novel heterocruciform intermediate. *J Virol* 2003;77:6245–6254, with permission from the American Society of Microbiology, and the authors.)

In vivo MVM replication has been found to evoke a DNA damage response (similar to AAV); H2AX, Nbs1, RPA32, Chk2, and p53 are phosphorylated and are recruited to MVM replication centers, where they co-localize with NS1.^{3,378} Parvovirus DNA replication takes place in discrete subnuclear structures sometimes known as PARs, which contain DNA polymerases α and δ .^{38,128,205}

Adeno-Associated Virus DNA Replication

The AAV genome is 4,500 to 5,000 nucleotides long and has palindromic terminal sequences that serve as the primers for DNA replication of AAV (see Fig. 57.5). AAVs have several forms of Rep with multiple functions in DNA replication, but no DNA polymerase or ssDNA binding protein, and additional factors are supplied by either the helper virus and/or the cell. Because of the AAV ITR and the evidence for inversion of the palindromic sequences at both termini, replication can occur by single-strand displacement^{190,416} (Fig. 57.8). The 3' terminal repeats fold over to form hairpin structures²⁸¹ that serve as primers for DNA synthesis⁴¹⁶ (see Fig. 57.8). Complementary strand synthesis continues either to the end of the parental template strand, forming a linear duplex molecule cross-linked at one end by the terminal hairpin, or the growing end of the complementary strand may become covalently linked to the hairpinned form of the ITR at the 5' end of the parental strand template to form a linear duplex cross-linked at both ends. Resolution is achieved by Rep (68 or 78) binding to the hairpin (which has a Rep binding sequence [RBS], as well as a secondary binding site on one of the cross-arms [see Fig. 57.5]) and nicking the original parental strand at the terminal resolution site (TRS), which is opposite the phosphodiester bond between the 3'OH of the primer and the 5'PO₄ of the first nucleotide inserted into the progeny strand.^{54,92,290,380} Rep covalently binds to the 5'PO₄ created at the nick,^{133,207,405} and the 3'OH serves as a primer for "repair" synthesis, filling in the resultant gap at the 5' end of the parental strand using the displaced hairpin sequence as the template.²⁰⁸ Thus, the original 3' end of the parental strand is transferred to become the 5' end of the new strand, and the terminal palindromic sequence is inverted. The 3' end of the newly synthesized strand may fold over to prime synthesis of another new strand, which can use both complementary strands of the original unit length duplex as a template to produce a linear, duplex dimer-length

FIGURE 57.8. The replication cycle of the adeno-associated viral DNA. The single-stranded DNA released from the virion after uncoating (top two possible forms) is extended from the 3' end of the hairpin to form a full-length hairpin. The hairpin is nicked at the terminal recognition site by Rep68 or rep78, leaving the Rep protein attached to the end of the DNA. The hairpinned end is unwound, and the 3' end formed by Rep cleavage is extended to the end of the template strand. The ends of each strand refold into their alternative self-base pairing hairpin structures, and full-length DNA synthesis from the 3' primer on the left end of the genome produces one single-stranded genome and one duplex structure, which can each serve as a substrate for additional round of replication. mT, monomer turnaround; dT, dimer turnaround replicative form; ss, single-strand viral DNA; mE, monomer extended replicative form, TRS, terminal recognition site.

molecule.^{313,416} The structure of the initial primer strand may potentially be either a linear single strand with a hairpinned 3' end or a single-stranded circle held together by H-bonding between the ITRs (see Fig. 57.8).

The large Rep proteins introduce site-specific nicks at the TRS, and their helicase activities are necessary for the hairpin unwinding during resolution of the hairpinned termini.^{208,408,462} The endonuclease activity selectively works on the hairpin structure, but poorly, if at all, on the linear duplex form of the same sequence.^{92,290} The Rep protein binds ATP, and its ATPase activity is required to unwind the double helix, but not for the endonucleolytic activity.^{208,408,462} The site-specific DNA binding and endonuclease activities have been mapped to the N-terminal domain of the larger Rep 68/78 proteins.⁴⁰⁶ The RBS is a tandem repeat of four copies of GAGC.^{92,290,380,407,457} Only two copies of the GAGC sequence are required to bind Rep, and there is apparently wide latitude in the number of copies of the tetranucleotide that are required for Rep to function.^{93,290,462} Rep 68/78 functions as a multimeric complex that binds to the RBS in the stem of the T-shaped structure of the folded ITR and also to a second site (RBS', GTTTC) that is at the tip of the cross arm farthest removed from the TRS^{54,380} (see Fig. 57.5). The TRS consists of a seven base sequence (3'CCGGT/TG5') that is recognized only on the correct strand.⁵⁵ The functional complex of Rep is a pentamer.¹⁹³ Once Rep is bound to the hairpin, Rep unwinds the stem of the ITR in a reaction that requires ATP hydrolysis to generate a single-stranded TRS,^{55,133,407} then the endonuclease active site carries out a transesterification to link tyrosine 156 of Rep to the 5' phosphate end of the nick.^{133,208,405} Rep remains covalently bound until packaging occurs and can be detected on the surface of the viral particle.³⁵⁷

The two smaller Rep 52/40 proteins can bind ATP and have helicase activity⁴⁰⁶ and may be involved in packaging of newly synthesized DNA strands into preformed capsids.⁸⁸ Although Rep 40 does not bind specifically to RBS, it does bind to ssDNA, dependent on two lysine residues at positions 404 and 406.⁴⁷⁶ The functional distinctions between the two isoforms of both Rep 78/68 and Rep 52/40 are not well delineated.

AAV DNA replication requires both cellular and helper virus components. Adenovirus encodes a DNA polymerase; however, AAV replication appears to use the cellular DNA polymerase δ . Data with regard to use of other cellular DNA polymerases is not conclusive. Recently, Nash et al³¹² have been able to reconstitute AAV DNA replication *in vitro* by fractionating extracts from adenovirus-infected cells. Cellular factors included replication factor 3, polymerase δ , proliferating cell nuclear antigen (PCNA), and the so-called minichromosome maintenance complex, as well as the AAV rep. Herpes simplex virus (HSV) encodes a DNA polymerase, and AAV replication will use that polymerase.^{300,456} Genetic studies of the helper virus gene products required for AAV DNA replication have identified several functions. Adenovirus ssDNA binding protein greatly enhances AAV DNA replication but is not an absolute requirement.^{80,217} HSV gene products include the UL30/UL42 HSV DNA polymerase; the helicase-primase complex of UL5, UL8, and UL52; and the UL29 product ICP8, which is the HSV ssDNA binding protein.^{300,456} Cells co-infected with AAV and helper viruses show co-localization of AAV DNA replication with both the viral ssDNA binding proteins and replication protein A (RPA), the cellular ssDNA

binding protein, as well as various proteins associated with the DNA damage response.³⁹⁰ In adenovirus co-infected cells, AAV replication can be associated with PML bodies; however, this is not seen with the HSV helper. Indeed, the PML bodies are dissociated as the consequence of HSV infection. Yet even when certain HSV ICP0 mutants were used as the helper and the PML bodies were maintained, AAV replication was not associated.¹⁵⁵ Recent cytochemical studies of HSV/AAV-infected cells have shown the association of various cellular proteins with AAV DNA replication; these include not only replication factor C (RFC), PCNA, and RPA but also many factors normally associated with cellular DNA repair, including the Mre 11/rad50/Nbs1 complex, Ku70 and -86, and other mismatch repair proteins.^{313,314} Nuclear high mobility group protein 1 (HMG1) binds to cruciform DNA¹¹⁰ and hence binds to AAV hairpins and Rep and stimulates Rep nicking, ATPase activity, and repression of AAV gene expression from the P5 promoter. The 52 kDa FK 506 binding protein FKBP52 binds to the single-stranded form of the D region of the ITR, the 20 nucleotide of the ITR beyond the palindrome.^{286,360} The phosphorylated form of the protein binds and inhibits DNA replication, whereas when the nonphosphorylated form binds, synthesis can occur. Phosphorylation is controlled by the epidermal growth factor receptor tyrosine kinase and correlates with the ability of AAV vectors to transduce cells in the absence of a helper virus.

Transcription

The AAV genome contains three transcription units with promoters at map positions 5, 19, and 40^{174,282,363} (Fig. 57.9). A single, functional polyadenylation signal is at map position 96,⁴¹² thus all three transcripts cover the 3' half of the plus strand. A single intron lies just beyond mp 40; four of six AAV mRNAs have this sequence excised.²⁶⁰ The ratio of spliced to unspliced mRNA species depends on binding of Rep 78/68 to the transcription template.^{363,364,432} Four mRNAs cover all or part of the ORF in the left half of the genome. Two initiate at the P5 (mp5) promoter, one is spliced and produces Rep 68, and the other is not spliced and forms Rep 78. The P19 promoter also produces two mRNAs producing Rep 52 and Rep 40. The P40 produces two major mRNAs splice variants; the one utilizing the upstream splice acceptor encodes VP1. In the variant, the VP1 initiator codon is spliced out, an ACG initiator codon is used to translate VP2,³⁰⁶ and the first AUG in phase is used as the initiator codon for VP3. An additional protein is encoded by an alternative ORF (nucleotides 2717–3340) within the *cap* gene; an unusual initiator codon CTG is used. The 23-kd protein has been shown to promote AAV2 capsid formation within the nucleolus.⁴¹⁰ In AAV5, most transcripts originating from P7 and P19 are polyadenylated at a site in the intron.^{362,474} Polyadenylation of P7 and P19 transcripts at the proximal site is governed by an element 5' to P41.

AAV transcription depends on the intracellular milieu. In a healthy cell, AAV represses its own transcription and DNA replication; however, limited Rep expression following second-strand DNA synthesis permits the establishment of latent infection. Cell stress by heat (39°C), ultraviolet irradiation, gamma irradiation, inhibition of protein synthesis by cycloheximide, and exposure to cytosine arabinoside or hydroxyurea can also allow AAV expression.⁴⁷⁰ Adenovirus helper factors include early regions (E) 1A, 1B, 2A, and 4 (ORF 6).^{8,370} The ICP0 gene

FIGURE 57.9. Transcriptional map of the adeno-associated virus type 2 (AAV2) genome, which includes three promoters (P5, P19, P40), the small intron donor (D), and acceptors (A1 and A2), the termination sites of the Rep and Cap messages. The major transcripts and the proteins they encode are shown, and the different open reading frames used are shown with different shading. (Adapted from Qiu J, Yoto Y, Tullis G, et al. Parvovirus RNA processing strategies. In: Kerr JR, Cotmore SF, Bloom ME, et al, eds. *Parvoviruses*. London: Hodder Arnold, 2006:252–273. Reproduced with permission of Taylor and Francis Books UK, and the authors.)

product of HSV-1 turns on AAV transcription and can activate transcription from an integrated latent viral genome.¹⁶⁷ Cellular transcriptional regulatory elements turn AAV RNA synthesis on and off, and the P5 promoter sequence contains binding sites for cellular, helper, and AAV transcriptional factors.^{253,345} Transcription is regulated during the replication cycle, and the final ratio of stable transcripts from P5, P19, and P40 are 1:3:18, respectively.

Autonomous Parvovirus Transcription

The transcriptional schemes of the autonomous parvoviruses are highly variable (Figs. 57.10 and 57.11). Many use promoters around map positions 4 and 38 to generate two transcripts, along with one polyadenylation signal near the right end of the genome.^{219,304,348} A small intron is between map positions 44

and 46, and a large intron is between map positions 10 and 39. For MVM, all messengers have the small intron spliced, although alternative splice donor and acceptor sites are used. Half of the P4 transcripts also have the larger intron spliced at alternative splice donor and splice acceptor sites, producing a total of nine mRNAs.^{115,219,304,368} Where the P38 transcript uses the upstream splice donor site, the mRNA is translated to VP1, whereas use of the downstream donor site gives VP2. The erythroviruses have one promoter at map position 6 but two polyadenylation signals: one near the middle of the genome and the other at the right end^{53,90,179,328} (see Fig. 57.11). Read-through of the internal polyA site occurs only with genome replication, and the large transcript is translated into the capsid protein.¹⁸⁰ The amdoviruses have promoters at map positions 3 and 36, and the mRNAs have complex splicing patterns.^{361,413,424} The

FIGURE 57.10. Transcriptional maps of the autonomous parvovirus minute virus of mice. The three major transcript classes (R1, R2, and R3) are shown relative to the viral genome, and the P4 and P38 promoters are indicated. The proteins encoded are shown as NS1, NS2, VP1/2, and the SAT proteins. The alternative open reading frames used are shown as different shading patterns. (Adapted from Pintel DJ, Gersappe A, Haut D, et al. Determinants that govern alternative splicing of parvovirus pre-mRNAs. *Semin Virol* 1995;6:283–290. With permission of author and Elsevier Press.)

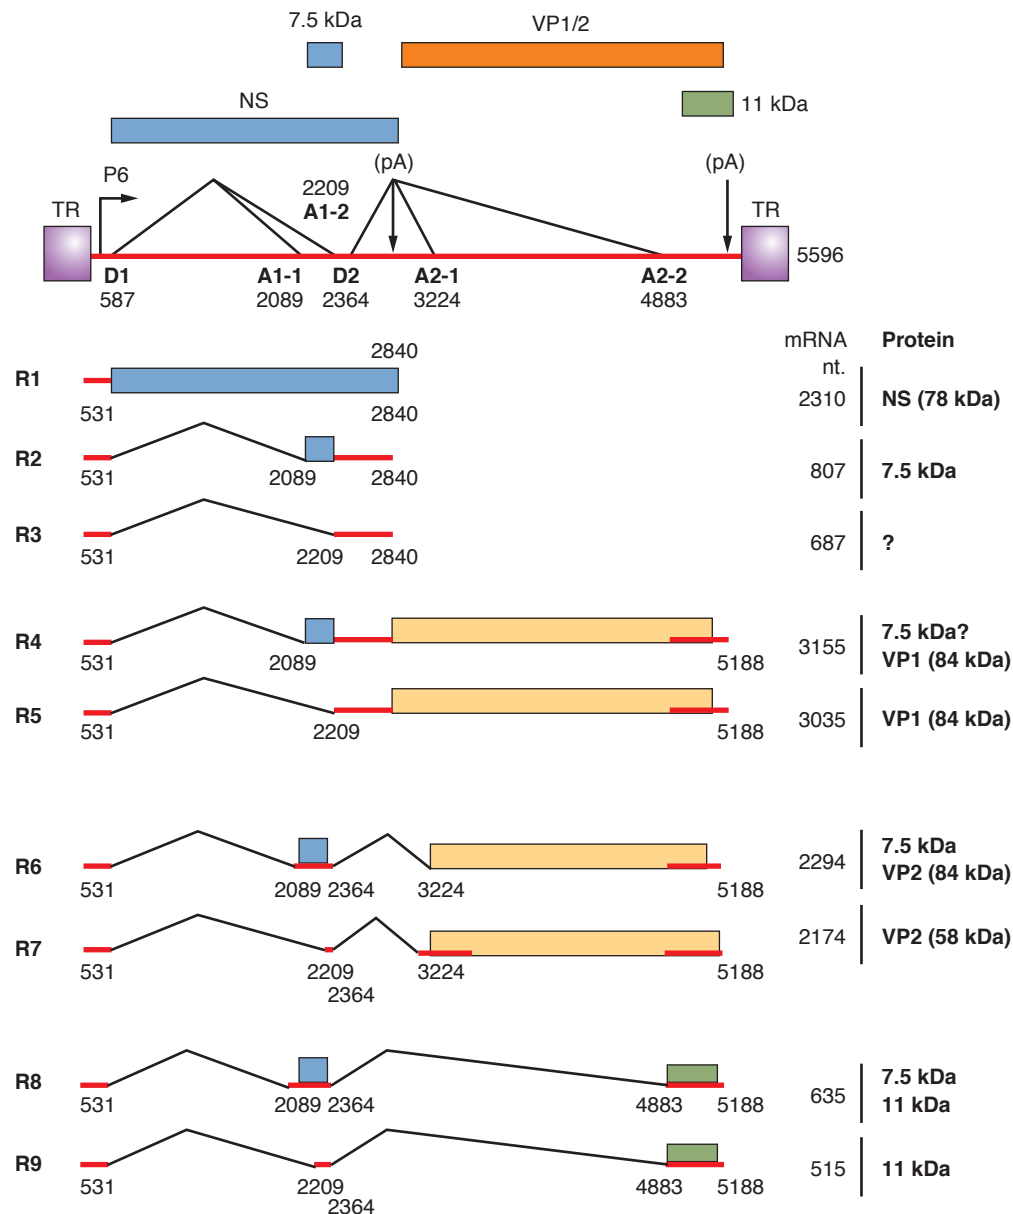

FIGURE 57.11. Transcription map of the B19 genome, showing the level of complexity of the RNAs produced by alternative splicing and polyadenylation. The main features shown include the viral promoter (P6), the various splice donors (D1 and D2) and acceptors (A1-1, A1-2, A2-1, A2-2), and the polyadenylation sites (pA). Other features shown are the open reading frames (*open* or *closed* boxes) and the products likely generated from each transcript. (Adapted from Guan W, Cheng F, Huang Q, et al. Inclusion of the central exon of parvovirus B19 precursor mRNA is determined by multiple splicing enhancers in both the exon and the downstream intron. *J Virol* 2011;85:2463–2468, with permission from the American Society of Microbiology and the authors.)

betaparvoviruses have promoters at map positions 4.5, 13, and 39; NS proteins and VPs are encoded in large ORFs in the left and right sides of the genome, and a small ORF that overlaps the 3' terminus of the NS ORF encodes NP1.^{89,424}

Regulation of transcription and posttranscriptional modification is complex. For MVM, splicing of the large intron (10–39) depends on splicing of the small intron (44–46),⁴⁸³ because the small intron assists entry of the large intron into the spliceosome. Modification of the polypyrimidine tract in the large intron relieves the requirement for initial splicing

of the small intron; however, nonsense mutations in the NS2 exon inhibit splicing of the large intron in a *cis*-active manner. NS1 transactivates P39 transcription; this activity has been localized to the C-terminal 129 amino acids.^{140,367} The three *cis*-active genomic sequences near P39 required for transactivation are a tar (transactivation response element at –139) to which NS1 binds in a reaction that is ATP dependent,^{98,277,278} an Sp1 site (–50), and the TATA box.^{7,278} NS1 can also interact with CBP, Sp1, TBP (TATA binding protein), and TFIIA in the absence of DNA.^{245,278} The promoter contains binding sites

for Sp1, CREB/ATF, E2F, and NF- κ B.^{134,135,160,346} Several regulatory mechanisms link MVM expression and replication to the cell cycle.^{134,135,346} The host range and tropism of MVM may be controlled in part at the level of P4 activation. Transgenic mice with β -galactosidase under the control of P4 showed expression in specific tissues and dependence on differentiation.¹³¹ Two MVM subtypes also differ in tissue specificity, as MVMi replicates in T lymphocytes, but not in fibroblasts, whereas MVMp has the reverse phenotype. Two amino acid sequence changes in the capsids control the phenotype and involve the control of the ratio of NS2 to NS1.⁹⁴ Mutation of a single base at the 3' splice site of the large intron enhanced the ability of MVMi to replicate in fibroblasts. NS2 interacts with the nuclear export protein Crm-1, and mutations enhancing MVMi NS2 binding to Crm-1 influenced MVMi replication in fibroblasts.^{94,275}

Protein Synthesis

Protein synthesis depends on the transcription. NS protein transcripts appear earliest in the course of infection, and one or both of NS proteins regulate gene expression.^{103,139,264} Both NS1 and NS2 are phosphorylated after translation.^{108,136,318,319} NS1 dimerizes prior to nuclear localization,^{319,320} and one interaction domain maps between amino acids 261 and 280.³⁵⁸ MVM NS2 is required for efficient virus growth in a host-dependent manner and is essential for growth in mouse cell lines and in animals.^{129,275,309,378}

Adeno-Associated Virus Proteins

The four NS proteins—Rep78, 68, 52, and 40—are named according to their apparent MWs, and protein amounts correspond to the levels of their transcripts. Rep78 and 68 are predominantly nuclear proteins, whereas Rep52 and 40 are also found in the cytoplasm.²⁹⁵ Rep52 retains helicase activity,⁴⁰⁶ whereas the Rep78/68 unique region plus a few amino acids shared with Rep52/40 are sufficient for nicking a single-stranded TRS substrate,¹³³ and a slightly smaller N-terminal region is sufficient for RBE binding.³²⁷ Rep sequences involved in terminal repeat binding have been mapped.^{132,165,288,289,440} Repression of the p5 promoter was most pronounced with Rep78, followed by Rep68 and Rep52.²⁰⁰ Transactivation of the p40 promoter was caused by either Rep78 or 68.⁴⁵²

VP1 to VP3 are translated from two alternatively spliced p40 mRNAs.³⁰⁶ The most abundant is translated to form VP2 from a nonconventional ACG codon and VP3 from a downstream AUG. VP1 is translated from the low-abundance spliced p40 message (see Fig. 57.9). All three proteins share the same ORF, and protein sequences begin with amino acid 1 of VP1, whereas VP2 begins at amino acid 138 and VP3 at 203.

Expression of the structural proteins alone leads to capsid assembly. VP2 is required for self-assembly; either VP1 or VP3 could be omitted, although VP1 and VP3 are required for infectivity.³⁷⁷ VP3, however, lacks an NLS⁴⁵⁹; if a heterologous NLS is fused to VP3, that protein can self-assemble into empty particles.⁴⁵⁹ At least one NLS has been mapped to the N-terminus of VP2¹⁹⁹; however, there appear to be redundant NLS.⁴⁶⁷ The heparan sulfate binding region of the AAV2 capsid protein has been mapped to two clusters of basic amino acids: residues 509 to 522 and 561 to 591.^{396,468} The N-terminus of VP2 and a portion of the N-terminus of VP1 are also on the capsid sur-

face. The N-terminus of VP3 and the C-terminus are internal to the capsid and essential for capsid structural integrity, and one mutant (R432A) makes only empty capsids.

Virion Assembly

Capsid proteins translated in the cytoplasm are transported to the nucleus, where they assemble³⁷² (see Fig. 57.4). The major capsid proteins can assemble alone into capsids that are structurally very similar to normal capsids,^{240,377,479} and those package viral DNA when they are expressed with replicating genome.⁴³⁸ However, capsids are only infectious when they contain the largest of the minor capsid proteins (VP1), likely because of their PLA₂ activity and nuclear localization functions.^{151,171,247,480}

DNA incorporation occurs by insertion of viral ssDNA into the preassembled capsid and requires the activity of viral larger nonstructural proteins, and the helicase activity is most likely involved in translocating the ssDNA into the capsid^{118,144,350,484} (Fig. 57.12). As described earlier, the polarity of DNA packaging of some viruses results from differences in the use of the sequences at each end of the genome for initiating replication, as when one sequence is used preferentially, and then one DNA strand is packaged more frequently. When replication initiates at both ends, the viruses package both DNA strands.¹¹⁹ After assembly, the capsids may be retained within the nucleus, translocated into the cytoplasm, or transported out of the cell in a process regulated at least in part by the phosphorylation state of the capsid proteins and the activation of gelsolin in the cytoplasm.^{33,147,270,479} (see Fig. 57.4).

Adeno-Associated Virus Latent Infection

AAV can establish a latent infection, allowing the genome to persist until conditions are favorable for the production of progeny. A cell culture model of AAV latent infection required inoculation of a fairly high multiplicity of infection in the absence of helper³⁴⁷ and then the genomes persisted for as many as hundreds of passages. The AAV genome can integrate into the cell genome; wild-type AAV2 integrated at a specific site (known as AAVS1) on the q arm of human chromosome 19 (q13.4), which contained a Rep binding site (RBS) and a terminal resolution sequence (TRS)^{203,242–244,383,441} (Fig. 57.13). Analysis of the sequences in the target showed that it included a 33-nucleotide sequence containing the RBS and the TRS separated by an 11-nucleotide spacer.^{265,296} Virus functions included the expression of Rep 78/68, which was required *in trans*, and the presence of the RBS.^{215,230,347} Viral DNA is generally integrated as a concatemer,^{91,203,293} and slightly more than a genome equivalent is required for successful rescue.¹⁷⁰ In the absence of Rep expression, integration occurs approximately randomly.²⁹³ The AAV genome can also survive for prolonged periods as an extrachromosomal element and be expressed in the absence of a Rep gene. The unusual ends of the DNA appear to allow it to resist intracellular exonucleases and may prevent DNA modification, which would turn off expression. The extrachromosomal forms of AAV DNA are concatemers that are thought to be circular.⁴⁰⁹ Many people likely harbor viral DNA sequences that can be reactivated, and the female genitourinary tract is a frequent site for AAV sequences.^{70,159} It is not clear whether the viral sequences are maintained in tissues as extrachromosomal elements, or as integrants, either at AAVS1 or at random locations. No negative

FIGURE 57.12. Possible pathways for parvovirus assembly and DNA incorporation, based on various studies of adeno-associated and autonomous viruses. Several mechanisms are possible; however, the current data proposes the assembly of capsids from viral protein subunits, possibly trimers (see Fig. 57.4), some of which remain as empty particles. The single-strand DNA is packaged during replication into the more or less intact capsids through the activity of the nonstructural or Rep protein. A final step involves the “maturation” of the capsids, which is seen as a small change in the buoyant density of the particle from 1.45 g/cm³ to 1.41 g/cm³. (Adapted from Kleinschmidt JA, King JA. Molecular interactions involved in assembling the viral particle and packaging the genome. In: Kerr JR, Cotmore SF, Bloom ME, et al, eds. *Parvoviruses*. London: Hodder Arnold, 2006:305–319. Reproduced with permission of Taylor and Francis Books UK, and the authors.)

consequences of AAV infection have been demonstrated in people in controlled studies.

PATHOGENESIS AND CONTROL OF TISSUE TROPISM

Parvoviruses appear to infect most species of vertebrates, as well as many arthropods and crustacea, and most are not associated

with disease. The major vertebrate pathogens are listed in Table 57.2. Autonomous parvoviruses require S-phase of the cell cycle for their replication, so there is an age dependence to many of the diseases seen. However, in general, only some dividing cells are targeted for infection, and the cell and tissue tropism controls the precise pathogenesis.³³⁶ Viral genes, including the capsid and NS2 sequences, govern the host range or pathogenicity of parvoviruses.^{29,50,274,337,434} There are likely many parvoviruses that cause only asymptomatic or very mild infections.^{14,15,218}

FIGURE 57.13. Schematic representation of the adeno-associated virus S1 region, the favored site of integration into the human chromosome position 19q13.42 chromosome, within the BamHI and EcoRI fragments as mapped by (REF and REF), where the EcoRI site is indicated as position 1. The sequence and position of the Rep binding site (RBS), terminal resolution site (TRS), and the MBS85 gene translation start sequence (ATG) are indicated, which allow Rep recognition and nicking. Locations of the GC-rich region, direct repeat sequence, chromosome 19 minisatellite sequence, DNase I hypersensitive site (DHS), and insulator element as indicated by arrows. (Adapted from Dutheil N, Linden RM. Site-specific integration by adeno-associated virus. In: Kerr JR, Cotmore SF, Bloom ME, et al, eds. *Parvoviruses*. London: Hodder Arnold, 2006:213–236. Reproduced with permission of Taylor and Francis Books UK, and the authors.)

TABLE 57.2 Major Parvovirus Pathogens of Vertebrates

Virus	Disease
Human parvovirus B19 and primate erythroviruses	Erythema in children, polyarthritides and arthralgia, transient aplastic crisis, fetal hydrops
Feline parvovirus (canine parvovirus and feline panleukopenia virus, mink enteritis virus)	Enteritis; generalized neonatal disease, myocarditis, ataxia following cerebellar hypoplasia
Porcine parvovirus	Fetal infection and death, abortion, infertility
Aleutian mink disease virus	Chronic immune complexes
Canine minute virus	Mild diarrhea, fetal or neonatal death
Minute virus of mice, rat virus, H1 virus of rats	Congenital fetal malformations, persistent subclinical infections
Goose parvovirus and duck parvovirus	Hepatitis and myocarditis

Tissue Specificity, Viral Entry, and Cryptic Infection

Viral tropisms may be determined by various factors. Certain MVM strains differ in cell tropism, and MVM(p) is restricted in T lymphocytes at the level of gene expression, whereas the related variant MVM(i) is permissive in those cells.⁴¹¹ The host range restriction is caused by mutations in the capsid.^{29,149,311} In other cells, transcription can occur, although DNA replication is inhibited. The narrow cell tropism of B19 virus for erythrocyte precursors is partly owing to the distribution of its receptor and to controls of gene expression.^{59,180} Some viruses show tissue-specific gene expression,²⁴⁸ and NS and capsid genes have been implicated in the PPV tissue tropism, whereas in MVM, NS2 has been implicated.^{129,147,309,376} No evidence of functional latency or genome integration of infectious autonomous parvoviral DNA has been detected during either active or abortive infections.

Fetal and Neonatal Infections

Fetal and newborn animals are highly susceptible to infection owing to the large number of dividing cells, and several parvoviruses cause fetal death or abortion. Maternal immunity completely protects the fetus, and maternal antibodies protect the newborn for some weeks after birth. Where immunity is lacking, fetal or neonatal infections can be caused by PPV,^{126,220,297} bovine parvovirus,⁴¹⁴ H-1 parvovirus,⁴²⁹ goose and duck parvovirus,⁵⁸ parvovirus B19,^{83,428} and AMDV.⁵⁶ Some infections are fatal, whereas in other cases the surviving fetus suffers severe sequelae such as congenital cerebellar ataxia by infecting cells in the developing cerebellum.^{232,430} Neonatal dogs infected with CPV may develop myocarditis.^{261,262} MVM infects renal vascular endothelial cells and lymphocytes in baby mice.^{65,214} Newborn mink infected with AMDV develop a severe respiratory distress syndrome subsequent to infection of type 2 alveolar pneumocytes, which proliferate in the neonatal period.^{12,446}

Older Animals

Parvoviral diseases in older animals result from the direct effects of virus infection on target tissues, as well as from the subsequent immune response. Direct infection of the target organ includes enteritis in CPV-infected dogs or FPV-infected cats, hepatitis in hamsters and geese, and erythrocyte aplasia in humans (B19 and related viruses) (reviewed in 52,61,122,336,478). Several disorders result from the host response to infection,^{102,109} the most dramatic being the chronic immune complex disease caused by persistent infection with AMDV, which can be worsened by vaccination.^{1,52} Certain PPV isolates induce immunologically mediated vesicular skin lesions in late-gestation swine fetuses,^{42,246} whereas the immune response likely causes the erythema seen in fifth disease and the polyarthropathy caused by B19 infection.^{464,478}

Parvovirus and AAV may show significant differences in host range or tissue tropism among closely related strains or isolates.^{50,84,86,87,130,323,337,340,434,468} Many sequences controlling these aspects of viral biology map to the viral capsids, mostly on the surface exposed regions.^{4,6,149,173,202,240,268,273,274,403} Although the capsid genes appear to be a major viral determinant of host range and pathogenicity, nonstructural gene products also play a role in some systems.^{66,129,275,309}

Human Parvoviruses

There are several human parvoviruses. The B19 and the related erythroviruses are associated with primary diseases, whereas the human parvovirus 4 (Parv4) and human bocavirus are of lower pathogenicity and are associated with diseases primarily in mixed infections with other pathogens. Parvovirus B19 infection may be subclinical. When present, disease is generally an acute, biphasic illness with a high viremia that peaks at days 8 and 9.^{19,96,351,356,464} (Fig. 57.14). Viremia is accompanied by nonspecific, influenza-like symptoms, including fever, malaise, and myalgia. Red cell aplasia coincides with viremia, leading to a drop in hemoglobin, reticulocytopenia, and modest lymphopenia and neutropenia. Appearance of specific immunoglobulin M (IgM) and IgG antibodies 10 to 14 days after inoculation is accompanied by classic fifth disease symptoms and with circulating immune complex formation.^{19,164} Acute infection with parvovirus B19 causes the childhood exanthem fifth disease (erythema infectiosum),^{21,63,96} which occurs after the viremic phase of infection and likely results from the host immune response to infection. Adults with acute B19 infection may suffer a symmetric polyarthropathy that can persist for weeks or months,^{463,464} likely resulting from the host immune response.

Parvovirus B19 is found in the nasopharynx, and transmission is probably through the upper airway,¹⁹ as well as by the transfer of contaminated blood products or tissues.^{221,349,466} The major sites of viral replication are the adult bone marrow and the fetal liver.^{251,252} Pathologic changes found in the hematopoietic tissues include giant pronormoblasts in bone marrow aspirates and fetal liver tissue sections with depletion of later erythroid precursor cells.^{17,83,249,252,329} Temporary depression of erythropoiesis results from B19 infection but is not significant in people without underlying hemolytic disorders. In people with a shortened red cell life span and reduced erythropoiesis, acute B19 infection causes TAC and a precipitous worsening of anemia.^{19,20,61,478} Predisposing conditions include sickle cell anemia, hereditary spherocytosis, enzymopathies, thalassemias,

FIGURE 57.14. Pathogenesis of B19 in humans. The graph shows the changes in the amounts of the virus or the immune response to the various viral capsid components at different times in an acute human infection. (From Kerr JR, Modrow S. Human and primate erythrovirus infections and associated disease. In: Kerr JR, Cotmore SF, Bloom ME, et al, eds. *Parvoviruses*. London: Hodder Arnold, 2006:385–416, with permission. Reproduced with permission of Taylor and Francis Books UK, and the authors.)

and acquired hemolytic anemias. Resolution of the crisis begins about 7 to 10 days after onset, coincident with the appearance of antiviral antibody and viral clearance. Viral replication occurs at high levels only in erythroid progenitor cells,³³⁰ and erythroid colony formation by the erythroid colony forming unit and the erythroid burst-forming unit are strongly inhibited by infection; susceptibility of marrow cells increases with erythroid differentiation.⁴²² Productive virus propagation depends on the presence of erythropoietin,^{397,398} and susceptibility is related to the effects of erythropoietin on erythroid differentiation.^{302,303}

Fetal infection may cause nonimmune hydrops fetalis characterized by severe anemia, high-output cardiac failure, and often fetal death.^{18,148,428,465} Erythroblasts in the fetal liver are infected, and fetal myocarditis may contribute to the pathogenesis.^{17,83,355} The risk for a fatal outcome is greatest during the first two trimesters, and fetal infection may persist after birth as pure red cell aplasia (PRCA).^{40,153,465} About 30% of maternal infections are vertically transmitted, and fetal death occurs in 2% to 10% of maternal infections; there is no evidence of congenital abnormalities after fetal B19 infection.^{60,428}

Simian parvoviruses are associated with severe chronic anemia and persistent simian parvovirus infection in cynomolgus monkeys immunosuppressed by infection with the type D simian retrovirus.^{62,324,325} Related parvoviruses are found in rhesus monkeys, pig-tailed macaques, chimpanzees, and gorillas.^{175,395} Acute diseases are similar to those seen in humans, with symptoms ranging from inapparent to very mild, although without the arthropathy seen in humans.^{62,325,326} An erythrovirus-like parvovirus has been found in Manchurian chipmunks.⁴⁷⁵

Canine and Feline Parvoviruses

CPV and FPV are very closely related and cause disease primarily in young animals, with a lessening of severity as the animals age.³³⁶ The relationship between the viruses is complex; FPV is found in cats, raccoons and related hosts, and CPV is a dog-specific variant that emerged in 1978.^{340,394} CPV has since undergone variation in antigenicity, as well as host range for cats and other carnivores.^{16,433} The viruses infect through the oral-nasal route, replicate in the pharyngeal lymphoid tissues, then spread as a free or cell-associated viremia to the other lymphoid tissues.^{74,75,124,125,283,284,299} There is a marked loss of lymphocytes from many tissues (thymus, lymph nodes, spleen, Peyer's

patches). The virus spreads to the small intestine, infecting the rapidly dividing cells in the crypts of Lieberkühn, resulting in a loss of epithelial cells from the small intestine and shortened, nonabsorptive villi and subsequent diarrhea.^{73,285} Animals that survive recover normally and are protected against reinfection by the immunity they develop.

Porcine Parvovirus

Infection of older pigs mostly is mild or subclinical. However, in pregnant pigs, infection can lead to fetal infection; those infected prior to reaching immune competence (55–70 days gestation) have an extensive infection and die.^{127,220,297} After infection of the sow, the virus takes approximately 15 days to reach the fetus, and early infection can result in fetal death and resorption or mummification.^{126,127,297} After approximately 70 days of gestation, the fetuses are generally less severely infected, and the virus replicates in the lymphoid tissues.⁶⁴ PPV has also been associated more rarely with poorly understood skin vesicular disease.²⁴⁶ Combined infections of PPV and porcine circovirus type 2 may cause a severe disease termed *postweaning multisystemic wasting syndrome*, which appears to result from the immune stimulation resulting from the PPV infection.^{13,181,188,259}

Aleutian Mink Disease Virus

AMDV mostly causes disease in mink of certain susceptible genotypes but commonly infects mink, and the same or related viruses can also infect skunks, ferrets, and foxes.^{52,154,211,263} Disease is age dependent; in neonatal mink, an acute disease results from infection of type II pneumocytes and pneumonitis owing to loss of surfactant production.¹¹ In older animals, or in young animals treated with antiviral antibodies, the disease is chronic and characterized by plasmocytosis, hypergammaglobulinemia, glomerulonephritis, arteritis, focal hepatitis, and death.^{10,12} Lesions in chronically infected mink result from viral antigen/antibody complexes that are not efficiently cleared.¹⁹¹ The (Aleutian) coat color mutation is linked to a lysosomal storage disease similar to the human Chediak-Higashi disease, in which the phagocytosed immune complexes are not degraded.¹⁸² Vaccination is not effective and may enhance the disease; however, control can be achieved by testing and culling infected animals, as transmission is relatively inefficient.

Rodent Parvovirus Diseases

Many different parvoviruses infect rodents, including several that infect experimental mice and rats, as well as wild mice and other rodents.^{44,45,214,216,471} Rodent parvoviruses can develop persistent infections but are not usually associated with overt clinical disease.^{161,213} They can also infect rodent and other cells in tissue culture and be introduced into animals by transfer of those cells.^{44,292,471} The viruses may cause fetal abnormalities or death owing to their tropism for dividing cells. Control is most effectively by physical isolation and barriers, by serologic or DNA testing, and culling of the infected animals or populations, with cesarean derivation of the young into a clean environment.^{216,451}

Other Pathogenic Parvoviruses

Goose parvoviruses can infect goslings of 8 to 30 days of age can result in focal or diffuse hepatitis and widespread degeneration of striated, cardiac, and smooth muscles.^{172,236} Duck parvovirus causes a similar disease in ducks. Bovine and rabbit parvoviruses are not commonly associated with clinical disease. Minute virus of canines (canine minute virus; canine bocavirus) is widespread in dogs.^{46,389} The infection is generally subclinical; in fetuses or neonatal puppies, the main target organs are the lung and small intestine.⁷⁸ The virus has been isolated from puppies with diarrhea, although mostly in conjunction with another enteric pathogen.³⁰¹

Dependoviruses

Natural AAV infections are assumed to occur via the respiratory or gastrointestinal route. It is not clear which tissues are the preferred sites of latency or infection in humans, although some evidence suggests that muscles may be involved. The virus has not been detected in human lung samples but is recovered from a small percentage of hematopoietic cells and from the female genital tract.^{159,178} AAV has been found at higher frequency (20%) in muscle biopsies.⁴²⁶ The chromosome 19 integration site is associated with the *MBS85* gene, and integration alters that gene expression.^{145,146,152} Skeletal muscle resists adenovirus and herpes infection, thus this could be a reservoir protected from rescue by AAV helper viruses.

IMMUNE RESPONSE, KEY ANTIGENS, AND VACCINATIONS

Immunity to parvovirus infection includes both antibody and T-cell responses. Antibodies protect animals against infection by most parvoviruses and aid in recovery, as antibody therapy can resolve chronic human infections with B19 and clear canine infections by CPV.^{157,250,298,315} The immune responses in hosts that recover protect for many years. The major antigens recognized by antibodies are the conformational epitopes of the capsids.^{272,385, 2009 #15684,415,460} Antibodies to the capsids of AAV can interfere with gene therapy.^{442,450} Other structures recognized by neutralizing antibodies include the VP1 unique region of the B19 virus^{307,375} and an exposed peptide of the VP2 N-terminus of CPV.²⁵⁸ Antibody may also induce the immune complex-mediated manifestations of some infections. Relatively little is known about the T-cell responses to parvoviruses; however, these are likely important in recovery from infection.^{156,209,225,400}

Vaccines

Modified live and inactivated or subunit vaccines have been developed against parvoviruses. In many cases, they can protect against infection. A candidate recombinant vaccine has been developed for B19.^{30,31,43} Modified live and recombinant vaccines protect dogs and cats against CPV and FPV,^{77,271} and vaccines against PPV are also successfully used.^{341,342}

EPIDEMIOLOGY

Prevalence and Incidence

Many parvoviruses appear to be widespread, and most circulate readily among the susceptible individuals. Parvovirus B19 infects almost all humans, and IgG antibody generally persists for life; 50% of children have anti-B19 antibodies by 15 years of age, as do more than 90% of elderly people.^{60,104,166} Viremia is relatively short lived, and although virus may be transmitted by blood, few donated blood units contain high titers of B19.^{105,221,241,294,404,437} B19 infections are seasonal, peaking in late winter, spring, and summer,⁶⁰ and they cycle in 3- to 4-year periods. Between 10% and 60% of susceptible schoolchildren and 20% to 30% of susceptible or adult school and daycare personnel can develop fifth disease in school outbreaks,^{60,96,169} and sibling-to-sibling transfer is probably a major path of transmission.²³⁹ Nosocomial transmission likely occurs but is difficult to distinguish from community-acquired infections.³⁹ Because of the resistance of parvoviruses to heat and solvents, virus may survive the inactivation treatments employed for blood products and pass through filters; thus, the virus can be spread throughout pooled preparations, although infections appear uncommon.^{237,466}

In normal CPV or FPV infections, virus is shed at very high titers in feces and can be found in places where infected animals are housed.³³⁶ Maternal antibodies protect animals against infection by CPV and FPV, and pups or kittens between 6 and 16 weeks of age with waning maternal immunity are highly susceptible.³⁵² Vaccination with modified live vaccines provides strong protection; however, that is blocked when maternal antibody is present.^{76,77}

Adeno-Associated Virus Infections

AAV infections most likely occur in the presence of an adenovirus or herpesvirus infection, and respiratory, fecal-oral, direct conjunctival, and sexual transmission have all been suggested.^{47,168,185,388} AAVs infect a wide variety of mammals; however, cross-species transmission is not known. AAV2, AAV3, and AAV5 have been obtained from humans in the presence of numerous adenovirus serotypes.^{32,48,49} AAV3 was isolated during an outbreak of adenovirus type 3 conjunctivitis among children and adults; it was found in conjunctival, throat, and fecal specimens.³⁸⁸ AAV5 was isolated from a male with a flat condylomatous genital lesion.³² AAV DNA (primarily AAV2) has been detected in peripheral blood cells, cervical biopsy samples, and tissues from spontaneous abortions, as well as tissue culture cells and adenovirus isolates.^{163,178,185,387,427} Antibodies to AAV can reduce the efficiency of gene transduction, and gene therapy vectors derived from a variety of serotypes are being examined to attempt to avoid antibody neutralization.^{183,184,379,482}

Treatments

A few specific treatments are used for most parvovirus infections. Chronic or persistent B19 infections can be treated with commercial immunoglobulin preparations.^{210,249,250}

ADENO-ASSOCIATED VIRUS AS A VECTOR FOR GENE THERAPY

AAV is being developed as a vector for human gene therapy owing to its persistent infection and lack of pathogenicity. Different AAV serotypes have different cell receptors and tissue tropisms or host ranges; as well, they offer the possibility of overcoming humoral immunity to a specific serotype.^{95,177,308} Current AAV vector genomes contain the transgene(s) and regulatory sequences between two copies of the AAV ITR, and no viral genes are expressed and little of the unique sequence of the AAV genome remains. The capacity of a vector based upon the AAV genome is approximately 4.5 kb,¹⁷⁶ although it is possible to include different parts of a transgene in two vectors and have them expressed as a spliced, functional protein product.^{143,256,343}

Production of AAV vectors involves the vector genome (transgene between two ITRs) in a plasmid; the AAV internal, unique sequences (minus the ITRs) in a plasmid; and required helper functions, such as the adenovirus or the HSV genes required for transcription and DNA replication. AAV vectors have been used to transduce cells *ex vivo*, as well as *in vivo* in intact animals and in people.⁷⁹ The vector is primarily maintained as an extrachromosomal element, although it may integrate into the genome.⁴⁰⁹ Transgene expression may be at high levels and maintained for more than a year in rodents and for several years in dogs.² It may be sufficient to functionally correct diseases, including hemophilia,¹⁹⁴ acute macular degeneration,³⁰⁵ diabetes,²⁰⁴ parkinsonism,²³⁵ and $\alpha 1$ antitrypsin deficiency.²⁷⁹ Animal models have included rodents, dogs, and subhuman primates. Vector has been administered *ex vivo* and *in vivo* intramuscularly, intravenously, bronchially, by the upper respiratory route, and by injection into the eye, and minimal toxicity has been observed.

Many clinical trials using various AAV vectors had been completed or are ongoing.⁷⁹ Among the diseases being targeted are cystic fibrosis, hemophilia B, Leber congenital amaurosis, arthritis, human immunodeficiency virus (HIV; vaccine), muscular dystrophy, hereditary emphysema, Parkinson, Canavan, Batten, Alzheimer, and malignant melanoma. Different routes of administration have been used, including intramuscular, hepatic artery, intracranial, intradermal, and *ex vivo*. In all of these trials, the vector has shown minimal or no evidence of toxicity. Clinical efficacy has been observed in patients with Leber congenital amaurosis²¹² and hemophilia B.¹⁹⁵ Other promising trials have involved Duchenne muscular dystrophy and $\alpha 1$ antitrypsin deficiency. Different AAV serotypes can show dramatically variant rates of transduction in various tissues; thus, clinical trials may involve different serotypes and alternative routes of administration.

Current vectors lack Rep proteins or Rep binding sites and therefore do not specifically integrate into the human genome.^{242,243,383} The transduced DNA remains within the cell primarily as extrachromosomal elements, and loss by dilution

may occur if the cells undergo cell division. Targeting site-specific integration may overcome the challenges of cell division, and vectors in which the Rep function is provided in *trans* may allow site-specific integration under conditions where the Rep gene remains extrachromosomal; and such vectors have been developed and appear to work in animal models.³⁶⁶

SUMMARY AND CONCLUSIONS

Parvoviruses include a wide variety of viruses that infect most animals, from mammals to crustaceans. Although many parvoviruses are associated with various acute and chronic diseases, there are many others that cause no or very mild disease, which are often only uncovered by DNA detection or sequencing methods. The small genomes encode two large genes that are expressed in various spliced versions, as well as several small transcripts and proteins that are often less well characterized. The viral capsids assemble from 60 copies of two or three forms of the same protein, and each variant protein has important functions for receptor binding and cell infection. The small size and limited genetic capacity of the viruses means that they highly depend on host cell functions for their replication and only complete their replication cycles in cells undergoing mitosis or those co-infected with a helper virus. The lack of pathogenicity and efficient transduction capabilities of the AAVs has made them a favored candidate for gene therapy in humans.

Perspective

HISTORY

The prototype circovirus, porcine circovirus (PCV), was first reported in 1974 as papovavirus-like and picornavirus-like particles in a contaminated porcine kidney cell line PK-15.¹⁰⁶ The name circovirus was proposed in 1982 when the viral genome was determined to be a circular single-stranded DNA molecule.¹⁰⁴ PCV was not known to be pathogenic¹⁰⁵ until 1997 when a variant strain, PCV type 2 (PCV2), was isolated from pigs with a wasting disease.² The PK-15 cell-derived virus was designated PCV1 to distinguish it from the pathogenic PCV2. The first circoviruses identified in avian species are chicken anemia virus (CAV) and subsequently psittacine beak and feather disease virus (BFDV), both of which are associated with diseases in birds. CAV was isolated in 1979,¹¹⁸ although its complete genomic sequence was not determined until 1991.⁷⁹ BFDV was first isolated as a novel virus with a single-stranded circular DNA genome in 1989 from cockatoos with beak and feather disease.⁹²

Definitive evidence of human infections by known porcine or avian circoviruses is lacking. Antibodies to PCV1 were reportedly detected in humans,¹⁰⁵ although subsequent studies could not confirm the initial report.^{3,28,39} Recently, novel circovirus-like DNA sequences were detected in stool samples from humans,⁵¹ although the biological and clinical significances of these novel circovirus sequences in humans remain unknown. The recent discovery of PCV1 and PCV2 DNA in

live-attenuated human rotavirus vaccines prompted the U.S. Food and Drug Administration (FDA) to temporarily suspend the use of rotavirus vaccines.^{4,111}

CLASSIFICATION

Viruses in the family *Circoviridae* infect mammalian and avian species. The genomic organization and replication strategy of circoviruses are similar to those of plant geminiviruses and nanoviruses. In fact, animal circoviruses may have evolved from a plant nanovirus through host-switch followed by a recombination event with a picorna-like virus in a mammalian host.³⁷ Two genera of circoviruses, *Circovirus* and *Gyrovirus*, have been recognized by the International Committee on Taxonomy of Viruses (ICTV). The genus *Circovirus* consists of at least 11 species including BFDV, PCV1, PCV2, canary, duck, finch, goose, gull, pigeon, starling, and swan circoviruses.¹¹⁵ CAV, which has larger virion and genome size as well as a different genomic organization, is the sole member of the genus *Gyrovirus*. The Torque teno virus (TTV) and mini-TT virus, which were once classified in the *Circoviridae*, have now been reclassified in a new family *Anelloviridae*.⁸ The “*Cyclovirus*” recently discovered from the stool samples of humans and chimpanzees may represent a previously unrecognized genus in the family *Circoviridae*.⁵¹

VIRION STRUCTURE

Circoviruses contain a single-stranded circular DNA genome enclosed within a capsid, which is presumably the only structural protein in the virion. Morphologically, members of the genus *Circovirus* appear as small, nonenveloped, icosahedral particles of approximately 15 to 20 nm in size (23,70; e-Fig. 58.1). The virion particles of CAV in the genus *Gyrovirus* are larger, with a diameter of 25 to 26.5 nm (23,36,64; Fig. 58.1). Members of *Circoviridae* all have a T=1 structure containing 60 copies of the capsid protein.²³ However, the capsids of genus *Circovirus* consist of 12 flat pentameric morphological units, whereas the capsid of CAV in the genus *Gyrovirus* consists of 12 pentagonal trumpet-shaped units. Therefore, the virions of the genus *Circovirus* have a smoother and more featureless surface than that of CAV of the *Gyrovirus* (23; Fig. 58.1).

GENOME STRUCTURE AND ORGANIZATION

The genome of *Circoviridae* is a single-stranded circular DNA molecule of 1.7 to 2.0 kb for genus *Circovirus*, and 2.3 kb for

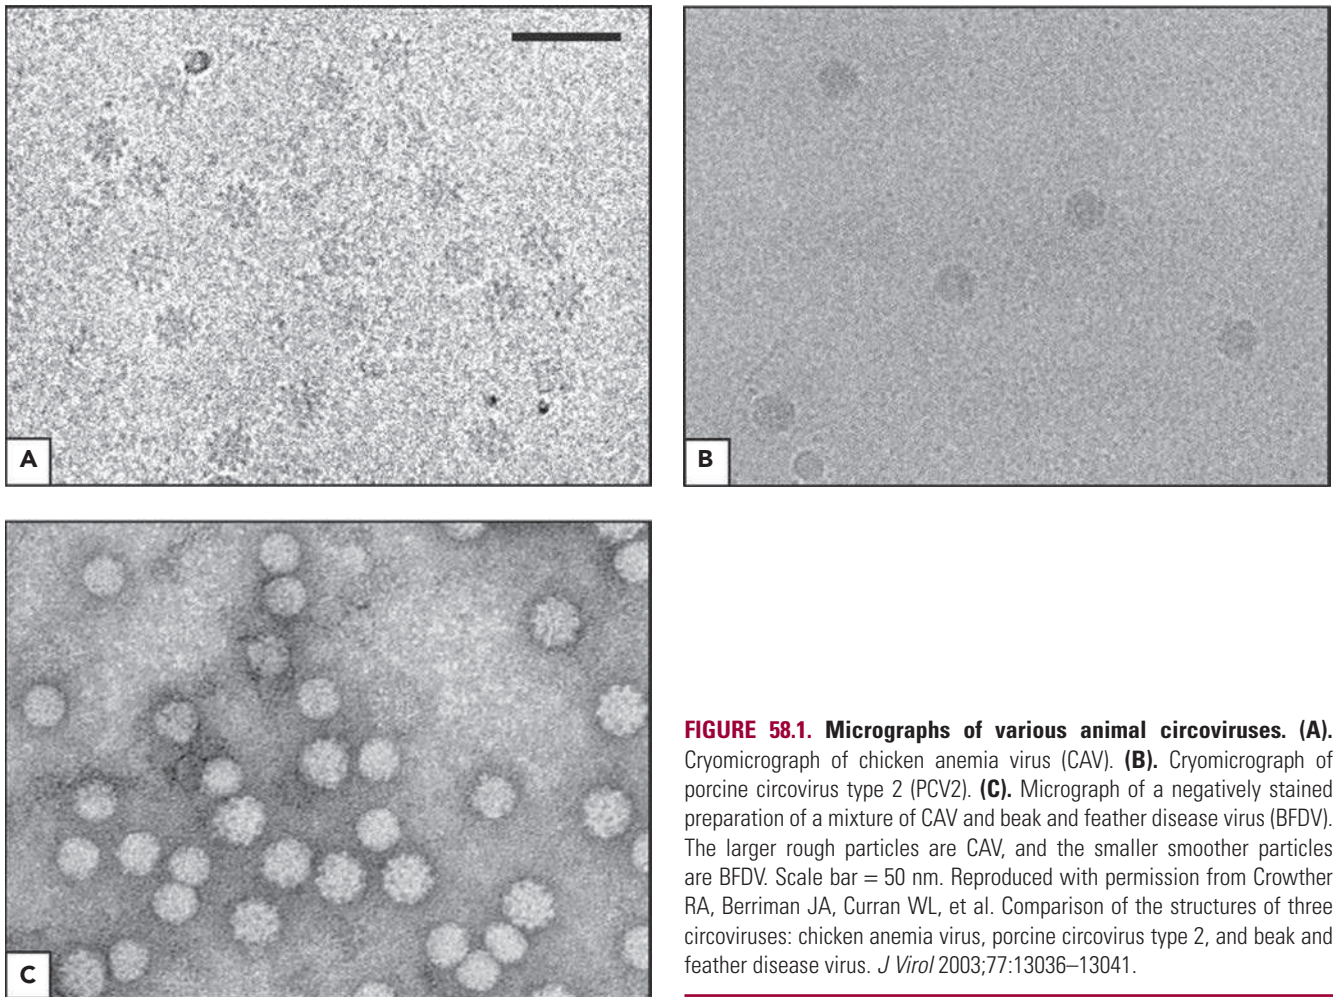

FIGURE 58.1. Micrographs of various animal circoviruses. (A). Cryomicrograph of chicken anemia virus (CAV). **(B).** Cryomicrograph of porcine circovirus type 2 (PCV2). **(C).** Micrograph of a negatively stained preparation of a mixture of CAV and beak and feather disease virus (BFDV). The larger rough particles are CAV, and the smaller smoother particles are BFDV. Scale bar = 50 nm. Reproduced with permission from Crowther RA, Berriman JA, Curran WL, et al. Comparison of the structures of three circoviruses: chicken anemia virus, porcine circovirus type 2, and beak and feather disease virus. *J Virol* 2003;77:13036–13041.

Gyrovirus CAV.^{96,115} These are the smallest DNA viruses known to infect mammals and birds, and the genome size is reduced to the absolute necessities for the two basic functions of a virus: copying and packaging of viral genome.

For the genus *Circovirus*, the genome contains two major open-reading frames (ORFs) coding for the replicase protein (Rep) and capsid protein (Cap), respectively. The *rep* and *cap* genes are oriented in the opposite direction resulting in an ambisense genome organization. The Rep and Rep' are produced from alternatively spliced RNA transcripts. An intergenic region between the 5' ends of *rep* and *cap* genes contains the origin of viral genome replication (*Ori*), which is characterized by a stem-loop structure with a nonamer motif in its apex (e-Fig. 58.2). Three or four hexamer repeat motifs adjacent to the stem-loop serve as the binding sites for Rep and Rep' to initiate rolling-circle replication of viral genome.^{33,61} The *rep* or *Ori* between PCV1 and PCV2 are fully exchangeable,^{5–7,29–31} indicating conserved functionality of these regions among members of the genus *Circovirus*.

The structure and organization of the CAV genome in the genus *Gyrovirus* is different from that of the genus *Circovirus*.^{22,79} The CAV genome is negative sense with approximately 2.3 kb, and contains three partially overlapping ORFs, a promoter-enhancer region, and a polyadenylation signal.^{74,87} The ORF1 codes for the VP1 capsid protein, and the ORF2 and ORF3

code for VP2 and VP3 nonstructural proteins. The ORF3 completely overlaps ORF2, whereas ORF2 partially overlaps ORF1. The promoter-enhancer region in the 5' NCR of CAV genome contains four or five 21-bp direct repeats (DRs) and a 12-bp insert between the second and third DRs.^{65,74} Host cell transcription factors bind to the DRs and the 12-bp insert, and at least two DRs and the 12-bp insert are required for efficient transcription and replication.^{73,74}

STAGES OF REPLICATION

Among the 11 species in the genus *Circovirus*, only PCV1 and PCV2 can be propagated *in vitro*. Although the CAV of the genus *Gyrovirus* can be propagated in cell cultures, very little is known regarding its replication. Therefore, the knowledge of circovirus replication is derived mostly from the studies of PCV1 and PCV2, and to a lesser extent, of CAV.

Attachment, Entry, and Uncoating

Glycosaminoglycans (GAG) heparin, heparan sulfate, and chondroitin sulfate B are attachment receptors for PCV2.⁶⁸ It is not surprising that PCV2 utilizes GAG as the general attachment receptors (33, e-Fig. 58.3), since the virus targets

multiple organs and tissues in infected pigs, even though cells in the monocyte and macrophage lineage are the preferential targets for PCV2 *in vivo*.⁹⁹ A yet-to-be identified specific receptor may be needed for more efficient binding and entry of PCV2 into cells.³³

PCV2 is internalized by dendritic cells (DCs), and the internalization was observed with both mature and immature cells including blood DCs, plasmacytoid DCs, and DC precursors, and thus suggestive of a nonmacropinocytic uptake of the virus.^{112,113} PCV2 virus-like particles (VLPs) quickly bind to porcine monocytic cells 3D4/31, and enter cells predominantly via clathrin-mediated endocytosis and require an acidic environment for infection.⁶⁹ The epithelial cells are also major targets for PCV2 *in vivo*. Although PCV2 quickly attaches to epithelial cells, virus entry was slow.⁶⁷ It appears that a dynamin- and cholesterol-independent, but actin- and small GTPase-dependent pathway, allows PCV2 entry and internalization leading to full replication in epithelial cells.⁶⁷ After entry, PCV2 is localized in the endosomes (33, e-Fig. 58.3). As the endosomal vesicles move toward the nuclear membrane and become acidic, a serine protease appears to be required for PCV2 release from the endosome, suggesting that a proteolytic cleavage of Cap may be a part of the uncoating process.^{66,68,69} PCV2 infection of untreated and chloroquine diphosphate-treated PK-15 cells was blocked by a serine protease inhibitor, suggesting that serine protease-mediated PCV2 disassembly is enhanced in porcine epithelial cells but inhibited in monocytic cells after inhibition of endosome-lysosome system acidification.⁶⁶

Transcription

A total of nine RNA transcripts were synthesized during productive PCV2 infection in PK-15 cells: Cap protein RNA (CR), five Rep-associated RNAs (Rep, Rep', Rep3a, Rep3b, and Rep3c), and three NS-associated RNAs (NS515, NS672, and NS0) (21; Fig. 58.2). Rep', Rep3a, Rep3b, and Rep3c are produced from Rep by alternate splicing. The three NS-associated RNAs are transcribed from three different promoters inside ORF1, and share only the 3' sequence with Rep.²¹ A stop codon introduced at the 5'-end of CR did not affect Rep-associated viral antigen or DNA synthesis.¹⁴ Altering the consensus dinucleotides at the splice junctions of the minor Rep- and NS-associated RNAs or introducing a stop codon in the abundant NS0 RNA also had no effect on viral protein or DNA synthesis. However, mutations resulting in truncated Rep or Rep' reduced viral protein synthesis by more than 99% and abolished viral DNA replication, indicating that both Rep and Rep' are essential for PCV2 replication.²⁰ In contrast to the pathogenic PCV2, a total of 12 RNAs were synthesized in PCV1-infected PK15 cells¹⁴ including the viral CR RNA, eight Rep-associated RNAs, and three NS-associated RNAs.¹⁴ The promoter for *cap* is mapped within the ORF1 (nt 1328-1252), and the promoter for *rep* is located in the intergenic region (nt 640-796) and overlaps the *Ori* of PCV1.⁶²

Several cellular gene transcripts were upregulated in both PCV2-infected PK-15 cells and affected tissues including two transcripts with homology to an RNA splicing factor (SPF30) and a hyaluronan-mediated motility receptor (RHAMM).¹⁰ Microarray analyses of the genes in lymph nodes of PCV2-infected pigs revealed altered expression levels in genes that are involved in innate immune defense (TLR1, CD14, and

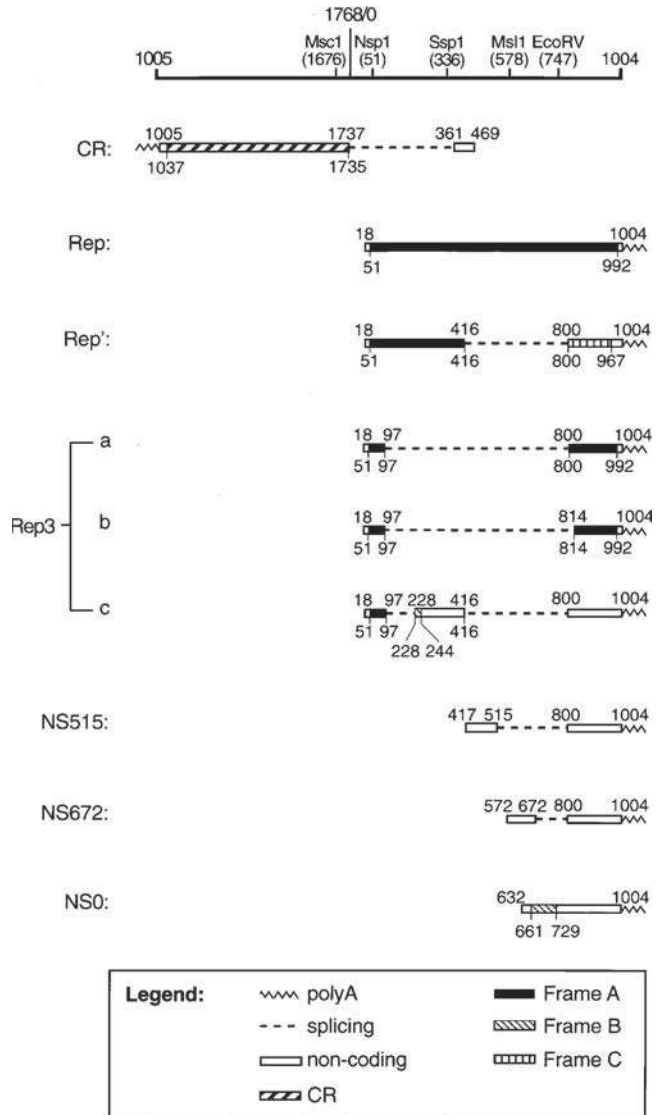

FIGURE 58.2. Summary of the porcine circovirus type 2 (PCV2) RNA transcripts. The schematic representation of the PCV2 genome with relevant restriction enzyme sites is shown on top. The RNA is annotated on top with nt coordinates that indicates the last nucleotide of each respective exon. The coding sequence of each transcript was shaded and their nt coordinates are indicated below each RNA. Reproduced with permission from Cheung AK. Transcriptional analysis of porcine circovirus type 2. *Virology* 2003;305:168–180.

CD180), immunosuppressed responses (FGL2 and GPNMB), pro-inflammatory signals (galectin-3) and fasting processes (Angiopoietin-like 4, ANGPTL-4), suggesting that PCV2 has developed an intricate mechanism to induce immunosuppression, inflammatory cell infiltration and weight loss in pigs.⁴⁹ PCV2, but not PCV1, induces interleukin 10 (IL-10) secretion by monocytic cells, which led to repression of IL-12 in peripheral blood mononuclear cells (PBMCs).⁴⁵ The PCV2 ORF3 protein binds to a regulator of G protein signaling (RGS), and co-localized with poRGS16 in lipopolysaccharide (LPS)-activated porcine PBMC. The poRGS16 appeared to participate in the translocation of ORF3 protein into the nucleus.¹⁰³

NF- κ B was activated concomitantly with PCV2 replication, and treatment of cells with an NF- κ B inhibitor reduced virus protein expression and virion production, suggesting that NF- κ B activation is important for PCV2 replication.¹¹⁴

Three viral proteins of CAV in the genus *Gyrovirus* are derived from a single 2.0-kb mRNA species.^{76,85} Several minor mRNA species of 1.6, 1.3, and 1.2 kb in size are also identified (42, e-Fig. 58.4). The 1.3-kb RNA had a splice site joining nt 1222 to nt 1814 and encoded head-to-tail VP1. The 1.2 kb RNA possessed a splice site joining nt 994 to nt 1095 and encoded several putative proteins with frameshift mutations. CAV contains a single promoter–enhancer region with four consensus cyclic AMP response element sequences that are similar to the estrogen response element consensus half-sites. These sequences are arranged as direct repeats, an arrangement that can be recognized by members of the nuclear receptor superfamily, and may provide a mechanism to regulate CAV activity in situations of low virus copy number.⁶⁵

Translation

The genome of genus *Circovirus* consists of two major ORFs: ORF1 encodes the Rep and Rep', and the ORF2 encodes Cap. Rep is translated from the full-length *rep* transcript, whereas Rep' is produced from a spliced transcript.³³ Both Rep and Rep' are essential for the initiation of virus replication.^{19,59,60} Mutation within motifs I to III and the putative dNTP-binding (GKS) box of the Rep and Rep' interfered with viral replication. Motifs I to III are essential for PCV1 *Ori* cleavage.¹⁰¹ The repression of *rep* promoter is mediated by binding of Rep to H1 and H2 hexamers in the *Ori* of PCV1; however, transcription of *cap* promoter is not influenced by viral proteins.^{33,60} Both Rep and Rep' co-localize in the nucleus of infected cells and form homomeric and heteromeric complexes.^{34,59} Three putative nuclear localization signals (NLSs) are present in the N-termini of Rep/Rep': NLS1 and NLS2 mediate nuclear accumulation, whereas NLS3 enhances the nuclear transport of Rep and Rep'.³⁴ PCV2 Rep interacted with an intermediate filament protein, similar to human syncoilin, and with the transcriptional regulator c-myc.¹⁰² The PCV Rep also binds three porcine cellular proteins^{1,35}: ZNF265 is an alternative component of the spliceosome, whereas VG5Q and TDG were linked to transcriptional regulation.

The Cap of the genus *Circovirus* can self-assemble into VLPs,^{11,70,117} and it elicits neutralizing antibodies in vaccinated animals.^{9,97} At least five different but overlapping conformational epitopes were identified within residues 47 to 63 and 165 to 200 and the last four amino acids at the C terminus of PCV2 Cap.^{50,57} Two amino acid mutations in the Cap, P110A and R191S, enhance the growth ability of PCV2 *in vitro* but attenuate PCV2 *in vivo*.³² The Cap localized in the nucleoli of PCV2-infected cells⁵⁴ and in the nucleoli of cells at an early stage of PCV1 infection.³⁴ The PCV Cap interacts with numerous cellular proteins^{35,102} including complement factor C1qB, E3 ubiquitin ligase family member MKRN1, and proapoptotic gene product Par-4.³³ The exact function of these cellular factors in PCV replication remains to be elucidated. An ORF3 has been identified in PCV1 but is truncated in PCV2. The *in vitro*–expressed ORF3 protein of PCV2-induced apoptosis through the activation of caspase 8 and caspase 3 pathways.⁵² The ORF3 protein interacts with pPirh2 and competes with p53 in binding to Pirh2 and mediates the deregulation of p53

homeostasis, leading to increased p53 levels and apoptosis of the infected cells.^{44,53} It was reported that abrogation of the ORF3 function attenuated PCV2 in pigs,⁴³ although other studies showed that PCV2 pathogenicity is not solely determined by ORF3.^{13,41} In fact, whether or not PCV2 infection causes apoptosis remains controversial.^{48,58,91,113}

The CAV genome encodes three proteins: the VP1 Cap and the VP2 and VP3 nonstructural proteins.^{94,108} The amino acid residue 394 of VP1 is a determinant of virus pathogenicity.¹¹⁶ The VP2 is a multifunctional protein that also serves as a scaffold protein during virion assembly.^{47,76,94} The VP2 has dual serine and tyrosine protein phosphatase activities,^{85,86} and mutations in VP2 attenuated CAV.⁸⁴ Both VP1 and VP2 are required to elicit neutralizing antibodies against CAV.^{27,47,75,77} The VP3 of CAV, also known as apoptin, induces apoptosis in chicken thymocytes and lymphoblastoid cells.⁷⁸ VP3 triggers the intrinsic mitochondrial death pathway, resulting in loss of mitochondrial membrane and release of cytochrome c and apoptosis-inducing factors in mitochondria.^{12,25,55} The VP3-induced apoptosis is independent of tumor suppressor p53, and Bcl-2 does not inhibit the VP3-induced apoptosis in tumor cells.^{24,26,95} Synthesis of VP3 alone induces apoptosis in human tumor cell lines, but not in normal human diploid cells,²⁴ and thus VP3 is considered as an anticancer agent.^{71,72}

Replication of Genomic DNA, Assembly and Release

After uncoating, the single-stranded circular viral DNA genome is converted to double-stranded DNA (dsDNA) DNA intermediate by host enzymes in the nucleus. Binding of Rep and Rep' to *Ori* unwinds the dsDNA intermediate to initiate genome replication.^{15–19,33} Viral genomes with mutations on either or both arms of the inverted repeats (IRs, palindrome) were still capable of synthesizing viral proteins and producing infectious viruses with restored or new palindromes, indicating that a flanking palindrome at *Ori* is not essential for initiation of viral DNA replication. A rolling-circle “melting-pot” model for circovirus DNA replication was proposed (15,18, Fig. 58.3). The Rep and Rep' complex binds, destabilizes, and nicks the *Ori* sequence to initiate leading-strand DNA synthesis.¹⁵ The four strands of the destabilized IRs exist in a “melted” configuration, and the minus-strand viral DNA and a palindromic strand serve as templates simultaneously during initiation or termination of viral DNA replication. The palindromic sequences flanking the *Ori* can potentially form single-stranded stem-loop cruciform structures that are essential for circovirus replication.¹⁸ Three conserved rolling-circle replication motifs (RCR-I, RCR-II, and RCR-III) and a deoxyribonucleotide triphosphates (dNTP)-binding motif were identified within PCV Rep and Rep'.^{33,40,100,110} Mutations of the conserved motifs negatively affect PCV replication.^{60,101} The RCR-II motif is involved in the nicking of the viral DNA, and the Tyr-93 residue within the RCR-III motif cleaves the phosphodiester bond to produce a 3'-hydroxyl group that serves as a primer for viral genome replication, and a 5'-phosphate of the cleavage product that covalently attaches to Rep and Rep'.^{100,110} After a round of replication, the newly synthesized viral genome DNA is cleaved again, and the 5'-phosphate is ligated to the 3'-hydroxyl group, resulting in the release of unit-length single-stranded monomer genomes.³³

The genome replication of the *Gyrovirus* CAV is also thought to be via a rolling-circle replication mechanism.^{94,109}

FIGURE 58.3. A: Schematic representation of the porcine circovirus type 1 (PCV1) *Ori*, indicating potential base pairing of the flanking inverted repeats. The genome sequence (1,759 nucleotides) and coordinates (1, 2, 3, etc.) are based on GenBank accession number AY184287. The nucleotide coordinates (3', 4', 5', etc.) are arbitrarily assigned to show the nucleotide complementarity of the palindromic sequences. The octanucleotide containing the presumed nick site (AGTATT↓AC) is boxed and indicated in bold. The palindrome is divided into six regions (right arm, RD3, RD7, and RD10; left arm, LD3, LD7, and LD11). The six-nucleotide tandem repeats located at nucleotides 13, 19, 30, and 36 (not perfect at nucleotide 38 and indicated by an asterisk) are in boxes. Relevant nucleotide sequences are assigned arbitrary positions (l-m-n-o-p-q-r-s and u-v-w-x-y-z) to assist in retracing the templates used during replication. **B:** The rolling-circle melting-pot replication model. (i) PCV1 *Ori* after Rep binding to the octanucleotide (prior to nicking) with the plus- and minus-strand genomes in proximity to each other. The destabilized environment (i.e., the melting pot) is enclosed by a dotted circle. (ii) Schematic representation of the DNA templates available during initiation of DNA replication after removal of the secondary structure in the model. The leading strand (L) displaces strand a, and uses strand a' or strand b as the template. (iii) Schematic representation of the DNA templates available during termination of DNA replication after removal of the secondary structure in the model. The leading strand (L) displaces strand b and uses the newly synthesized strand a_N or strand b' as the template. The plus-strand genome is indicated in black, the minus-strand genome is indicated in blue, and the potential base-pairing opportunities available for the current round of DNA replication are indicated in red. Reproduced with permission from Cheung AK. Palindrome regeneration by template strand-switching mechanism at the origin of DNA replication of porcine circovirus via the rolling-circle melting-pot replication model. *J Virol* 2004;78:9016–9029.

Homologous recombination occurs in cloned head-to-tail repeat replicative form of CAV genomes.¹⁰⁹ The VP1 contains a three-amino acid motif associated with rolling-circle replication.¹⁰⁷ The phosphatase activity of VP2 is important but not required for CAV replication.^{85,86} The VP3 is essential for completion of CAV life cycle as truncated VP3 lacking the C-terminal 11 amino acid residues failed to induce apoptosis.^{74,78}

PATHOGENESIS AND PATHOLOGY

Porcine Circovirus-Associated Diseases

PCV2 is associated with various disease conditions in pigs including postweaning multisystemic wasting syndrome (PMWS) and porcine dermatitis and nephropathy syndrome (PDNS), collectively known as porcine circovirus-associated

diseases (PCVADs).^{38,80,89} The oronasal exposure is likely the natural route of PCV2 transmission,⁹⁶ although pigs can be experimentally infected via intramuscular, oral, oronasal, and intrauterine routes of inoculation.^{56,81–83} Lymphoid depletion and histiocytic replacement are characteristic lesions in lymphoid tissues (80, e-Fig. 58.5). PCV2 is likely shed through respiratory and oral secretions, urine, and feces of infected pigs.⁸⁰ The interaction of PCV2 with the host immune system is a critical factor in PCV2 pathogenesis. Immunostimulations by co-infecting agents such as porcine reproductive and respiratory syndrome virus (PRRSV) or by adjuvants such as keyhole limpet hemocyanin exacerbate PCVADs.^{80,89} An increase in IL-10 and proinflammatory cytokines such as IL-1 and tumor necrosis factor α (TNF- α) and a decrease in IL-2 and IL-4 expression were observed in PCV2-infected pigs with PCVAD.⁸⁹ An interferon-stimulated response element (ISRE) sequence was identified in the Ori of PCV2 genome. When present in the context of intact virus but not in isolation, the ISRE influences the interferon-mediated enhancement of PCV2 replication *in vitro* and plays a potential role in viral pathogenesis *in vivo*.^{88,90}

Psittacine Beak and Feather Disease (PBFD)

PBFD, caused by BFDV of genus *Circovirus*, is one of the most frequently diagnosed viral diseases in psittacine birds.^{92,115} BFDV is now known to infect more than 60 different species of psittacine birds, and circovirus infections are common in many other avian species. The natural routes of exposures are thought to be by way of aerosolized virus particles or direct ingestion of contaminated materials. BFDV has tropism for rapidly dividing cells in mitosis stage such as basal follicular epithelium, lymphoid tissues, and intestinal epithelium. Virus transmission is through virus shedding in feather dander followed by fecal shedding and feeding of chicks with regurgitated crop contents. Gross pathological lesions include feather loss and dystrophy, and beak deformities. Microscopically, necrosis and inflammation are seen in dystrophic feathers. Lymphofol-

licular hyperplasia with necrosis and lymphoid depletion are commonly seen in lymphoid tissues of BFDV-infected birds.¹¹⁵

Chicken Infectious Anemia (CIA)

The natural route of exposure for CAV is likely oral.⁹³ Feces from infected chickens are the main source of virus for horizontal transmission. Vertical transmission in commercial flocks through hatching eggs is an important means of virus dissemination. Under field condition, vertical transmission occurs for a period of 3 to 9 weeks after exposure to CAV. Gross lesions include thymic and bone marrow atrophy, and less commonly bursal atrophy. Hemorrhagic-aplastic anemia syndrome characterized by intracutaneous, subcutaneous, and intramuscular hemorrhages is associated with severe anemia in CAV-infected chickens. Microscopically, CAV-infected chickens are characterized by generalized lymphoid atrophy and depletion, and panmyelophthisis. Infection of hemocytoblasts in the bone marrow and lymphoblasts in the thymus cortex in the early infection stage (6 to 8 days post-infection) cause a rapid depletion of these cells by apoptosis with drastically reduced numbers of erythrocytes, white blood cells, and thrombocytes.⁹⁸

EPIDEMIOLOGY AND CLINICAL FEATURES

PCVAD affects grower pigs of 5 of 18 weeks of age, and rarely occurs in 1- to 3-week-old pigs, presumably due to maternal antibody protection.⁶³ PCV2 infection is widespread worldwide, with 100% seropositivity in some herds; however, the morbidity is low and only a small proportion of infected animals (5% to 30%) actually develop clinical PCVAD.^{38,80,89} PCV2a and PCV2b genotypes, which differ by as much as 10% at nucleotide sequence level, are most prevalent worldwide.⁶ The main clinical signs of PCVAD include progressive weight loss or decreased rate of weight gain, paleness or icterus, and gauntness and ill thrift (80, Fig. 58.4A). The infected pigs may

FIGURE 58.4. A: An 8-week-old pig experimentally co-infected with porcine circovirus type 2 (PCV2) and porcine parvovirus (PPV) showing icterus and a poor body condition typical of systemic porcine circovirus-associated disease (PCVAD). **(B):** A 12-week-old pig with from porcine dermatitis and nephropathy syndrome (PDNS). The perineal region, ventral abdomen, and legs are covered with raised coalescing red-purple lesions. Reproduced with permission from Opriessnig T, Meng XJ, Halbur PG. Porcine circovirus type 2 associated disease: update on current terminology, clinical manifestations, pathogenesis, diagnosis, and intervention strategies. *J Vet Diagn Invest* 2007;19:591–615.

also experience labored respiration with coughing and diarrhea (e-Fig. 58.6). PCV2 is associated with a number of diseases including pneumonia, enteritis, reproductive failure, and PDNS (Fig. 58.4B).^{80,89}

BFDV infection is usually seen in young psittacine birds younger than 3 years of age and young pigeons of less than 1 year of age, although older birds can also be infected. In general, circovirus infection in birds is associated with high morbidity but low mortality. The prevalence of BFDV infection varied in wild and captive bird populations. For example, approximately 41% to 95% of the free-ranging psittacine birds in New South Wales are seropositive, whereas 5% of the captive birds in the United States are positive for BFDV.¹¹⁵ Mortality and clinical signs in BFDV-infected birds varied dependent on the age, species, and concurrent infection status. The most common signs in circovirus-infected pigeons include poor performance, diarrhea, and ill-thrift, whereas loss of flight and tail feathers are the main clinical signs in turtle doves.¹¹⁵ The majority of the infections are subclinical.

CAV infection is ubiquitous in chicken flocks worldwide. CAV infection of chickens of 2 to 4 weeks of age induced anemia, which is characterized by hematocrit values ranging from 6% to 27%. The mortality is about 10% to 20%, but generally does not exceed 30%. Surviving chickens completely recover from anemia by 20 to 28 days postinfection, although secondary bacterial or viral infection may slow down the recovery process. Chickens develop age resistance to CAV-induced anemia by approximately 3 weeks of age.⁹³

DIAGNOSIS, PREVENTION, AND CONTROL

The diagnosis of clinical PCVAD requires the demonstration of characteristic pathological lesions associated with the detection of PCV2 antigen or DNA in the affected tissues.⁸⁰ Prior to the availability of vaccines, good herd management practices, co-infection control, and disinfection of animal facilities can minimize the impact of PCV2 infection. At least four commercial vaccines are available against PCV2 infection and PCVAD,^{6,7,30,31,46} and these vaccines are very effective. Definitive diagnosis of circovirus infections in birds requires the detection of viral antigen or DNA in affected birds. Virus isolation is not possible for most circoviruses. Currently, there is no commercial vaccine against BFDV, and thus control of circovirus infection in free-ranging birds is difficult. CAV is the only avian circovirus that can be propagated in lymphoblastoid T-cell lines (MDCC-MSB1 and MDCC-JP2) and B-cell line (LSCC-1104B1). Virus isolation in susceptible cells and detection of CAV DNA and antigen in tissues are means of diagnosis of CAV infection. Commercial live-attenuated vaccines against CAV are used to immunize chickens of 9 of 15 weeks of ages. Complete elimination of CAV from chicken flocks is not realistic, and thus good management and hygiene procedures are important to minimize the impact caused by CAV infection.

PERSPECTIVE

Members of the *Circoviridae* are associated with several important animal diseases including PCVAD in pigs and PBFD and CIA in avian species. Although circovirus-like DNA sequences

have recently been detected in stool samples from humans, their biological significances remain unclear. The discovery of porcine circoviruses in live-attenuated human rotavirus vaccines raised a concern of vaccine safety, although definitive evidence of zoonotic human infections by animal circoviruses is still lacking. Only porcine circoviruses and CAV can be propagated *in vitro*, and a specific cellular receptor(s) for circoviruses has not yet been identified. Many steps in the circovirus life cycle including uncoating, replication, assembly, and release are poorly understood. Future studies are warranted to elucidate the molecular mechanism of circovirus pathogenesis, identify cellular and viral factors that determine species and tissue tropisms, assess the zoonotic potential of animal circoviruses, and determine the clinical significances of novel circovirus-like sequences in humans and farm animals.

with a hole running down their long axis, plus one capsomeric structure that serves as the portal for packaging and release of the viral genome (the complex of the core and capsid is the nucleocapsid); an amorphous-appearing, sometimes asymmetric material that surrounds the nucleocapsid and is designated the tegument; and an envelope containing viral glycoprotein spikes on its surface. Based on the morphologic criteria, highly divergent viruses with hosts that range from bivalves to humans have been identified as herpesviruses (Fig. 59.2). Originally classified into a single family, the availability of extensive nucleotide sequence data led to establishment of a new taxonomic order, the *Herpesvirales*,^{28,102} that encompasses three virus families: the herpesviruses of mammals, birds, and reptiles (the *Herpesviridae*),¹⁰⁰ herpesviruses of fish and amphibians (the *Alloherpesviridae*),⁹⁹ and herpesviruses of bivalves (the *Malacoherpesviridae*).¹⁰¹ This and subsequent chapters in this book are concerned primarily with viruses that have long been recognized as the family *Herpesviridae*.

The objectives of this chapter are to provide definitions and examples of many of the terms and concepts that are relevant across the diverse collection of herpesviruses (a glossary is provided in [e-Table 59.1](#)). Briefly summarizing such a broad area of active research can be accomplished only at the cost of oversimplification and overgeneralization. Subsequent chapters will delve into most of these areas in much greater depth. Students, especially, should understand that the paradigms presented here represent significant opportunities for conceptual and experimental challenge.

DISTRIBUTION IN NATURE

Herpesviruses are highly disseminated in nature. Most animal species have yielded at least one herpesvirus and frequently several distinct herpesviruses on examination. Inasmuch as few herpesviruses naturally infect more than one species, the number of herpesviruses in nature is likely to exceed the more than 200 identified to date. Thus far, nine herpesviruses have been identified that have humans as their primary host: herpes simplex virus 1 (HSV-1), herpes simplex virus 2 (HSV-2), human cytomegalovirus (HCMV), varicella-zoster virus (VZV), Epstein-Barr virus (EBV), and *Human herpesviruses 6A, 6B, and 7* (HHV-6A, HHV-6B, HHV-7), and Kaposi's sarcoma-associated herpesvirus (also known as HHV-8). Some key properties of many of the known herpesviruses are listed in [Table 59.1](#), and a more comprehensive list of viruses is provided in [e-Table 59.2](#). We have not tabulated the many herpesviruses identified primarily on the basis of small segments of nucleotide sequence (e.g., 35,36 and references therein).

*Who made the world I cannot tell;
'Tis made, and here I am in hell.
My hand, though now my knuckles bleed,
I never soiled with such a deed.*

A. E. Housman, No. XIX in *More Poems*

DEFINITION

Inclusion in the Family *Herpesviridae*

Herpesviruses have historically been defined based on the architecture of the virion (Fig. 59.1). A typical herpesvirion consists of a core containing a linear double-stranded DNA (dsDNA, ranging from 124–295 kb in length); an icosahedral capsid approximately 125 nm in diameter containing 161 capsomeres

FIGURE 59.1. Herpesvirus morphology as visualized by transmission electron microscopy. **A:** Schematic representation of the herpesvirion seen through a cross-section of the envelope with spikes projecting from its surface. The sides of the icosahedron forming the capsid show twofold symmetry. The irregular inner perimeter of the envelope is meant to represent the occasional asymmetric arrangement of the tegument. **B:** An intact negatively stained HSV-1 virion. The intact envelope is not permeable to negative stain. The diameter of the virion is approximately 120 nm. **C:** A HSV-1 capsid exposed to negative stain and showing twofold symmetry matching the diagrammatic representation of the capsid in **A**. **D:** HSV-1 nucleocapsid containing DNA permeated with uranyl acetate. The electron micrograph shows the presence of thread-like structures 4 to 5 nm wide on the surface of the core. **E–G:** Electron micrographs of thin sections of HSV-1 virions showing the core cut at different angles. The preparation was stained with uranyl acetate and counterstained with lead citrate. The DNA core preferentially takes up the stain and appears as a toroid with an outer diameter of 70 nm and an inner diameter of 18 nm. The toroid appears to be suspended by a fibrous cylindrical structure. The micrographs show the toroid seen looking down the hole (**E**), in cross-section (**F**), or from the side (**G**). The electron micrographs shown in **D** to **G** are from Furlong et al.⁴¹ **H, I:** Segmented surface rendering of a single virion tomogram after denoising. Outer surface showing the distribution of glycoprotein spikes (yellow) protruding from the membrane (blue) (**H**). Cutaway view of the virion interior, showing the capsid (light blue) and the tegument “cap” (orange) inside the envelope (blue and yellow) (**I**). pp, proximal pole; dp, distal pole. Bar = 100 nm. (**A, B, C, H, I** from Grunewald K, Desai P, Winkler DC, et al. Three-dimensional structure of herpes simplex virus from cryo-electron tomography. *Science* 2003;302:1396–98, with permission. **D** through **G** from Furlong D, Swift H, Roizman B. Arrangement of herpesvirus deoxyribonucleic acid in the core. *J Virol* 1972;10:1071–1074, with permission.)

BIOLOGICAL PROPERTIES

Members of the family *Herpesviridae* share four significant biological properties:

1. They specify a large array of enzymes involved in nucleic acid metabolism (e.g., thymidine kinase, thymidylate synthetase, dUTPase, ribonucleotide reductase), DNA synthesis (e.g., DNA polymerase, helicase, primase), and processing of proteins (e.g., protein kinases), although the exact array of enzymes may vary from one herpesvirus to another (Table 59.2).
2. Virus gene transcription, synthesis of viral DNA, and nucleocapsid assembly occur in the nucleus. Most virions

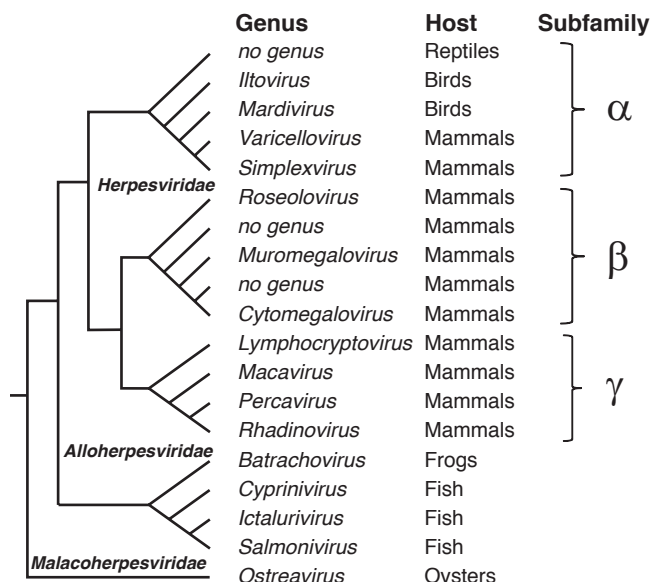

FIGURE 59.2. Major phylogenetic relationships and taxonomic subunits within the order Herpesvirales.¹⁰² The schematic shows branching patterns, not evolutionary distances.

acquire at least part of their tegument and are enveloped in the cytoplasm.

3. Production of infectious progeny virus (lytic infection) is generally accompanied by the destruction of the infected cell.
4. The herpesviruses examined to date employ cellular latency as a mechanism for lifelong persistence in their hosts (Fig. 59.3).

Herpesviruses also differ with respect to many of their biological properties. Some have a wide host cell range, multiply rapidly, and quickly destroy the cells they infect (e.g., HSV-1, HSV-2). Others have a narrow host cell range (EBV, HHV-6) or a long replicative cycle (HCMV). Herpesviruses can differ substantially with respect to the details of the mechanisms they use to manage host responses to infection and in the pathogenic mechanisms and clinical manifestations of diseases they cause.

NOMENCLATURE AND CLASSIFICATION

Herpesvirus Species

The definition of viral species accepted by the International Committee on Taxonomy of Viruses (ICTV) is “A virus species is a polythetic class of viruses that constitutes a replicating lineage and occupies a particular ecological niche”.¹²⁵ Consistent with this, “A herpesvirus may be classified as a species if it has distinct epidemiologic or biological characteristics and a distinct genome that represents an independent replicating lineage”.¹⁰² Several circumstances have arisen that might seem to challenge these definitions, but as illustrated here, the definition allows resolution of the issues.

The EBV variants, EBV-1 and EBV-2, differ markedly in several EBNA gene sequences. The differences lead to differ-

FIGURE 59.3. Outcomes of lytic and latent infections at the cellular and organismal levels. Thicker arrows represent more common events.

ences in some biological properties, including transforming potential. However, the variants do not occupy distinct ecological niches, the differences map to a small number of genes, and intermediates carrying one variant allele at one locus and the other variant allele at another locus have been detected. Thus, the EBV variants are recognized as allelic variants of the same species. At least two alleles have been identified of the KSHV K15 gene, which maps at the right end of the unique segment of the genome.¹⁰⁵ As for the EBV variants, recombinants have been detected between viruses encoding the different K15 alleles; thus, this represents another example of intraspecies allelic variation. It is possible that the EBV and KSHV allelic variants represent early steps in speciation. The process of adaptation to a specialized niche would likely result in the gradual emergence of a new virus lineage characterized by additional mutations across its genome, a unique epidemiology, and reduced biological fitness of recombinants with the parental lineage. The net product would be a new virus species.

Species Nomenclature

Two forms of nomenclature are employed for herpesviruses: an informal (also known as vernacular or colloquial) nomenclature that often traces to the early days of virology, and a formal nomenclature that is sanctioned by the ICTV. For example, the virus informally known as Epstein-Barr virus (EBV) is formally known as *Human herpesvirus 4*. Table 59.1 and e-Table 59.2 include formal and informal names for each virus. In the ICTV-endorsed formal nomenclature, herpesvirus names consist of the family, subfamily, or genus of the natural host of the virus, the word “herpesvirus,” and a serial Arabic number (e.g., *Cercopithecine herpesvirus 1*; Table 59.1). Human herpesviruses are an exception to the host name rule (e.g., *Human herpesvirus 7*). ICTV-recognized virus species names are italicized, and the first letter of the first word of the name is capitalized.¹²⁴ It has been proposed to rename herpesvirus species according to their subfamily, for example, *Human herpesvirus 1* would be renamed as *Human alphaherpesvirus 1*, but this has not been formally approved.

The host name–serial number nomenclature system was adopted in 1973^{106a} in an attempt to rectify problems associated with earlier systems in which viruses were named based on their disease associations, discoverer, geographic source, or whatever inspired the discoverer. Some viruses were given multiple names, and some names were applied to multiple viruses. Naming viruses after their associated diseases caused problems because

^aThe table was extracted and extended from information compiled by the *Herpesvirales* Study Group of the International Committee on Taxonomy of Viruses (ICTV). For details, see refs. 24,56,100,102,107,108.

^bFormally recognized HV species are italicized. Information about hosts is in bold.

^cRetired formal names are in brackets.

^dGenus designations: *Alphaherpesvirinae*: S, *Simplexvirus*; V, *Varicellovirus*; M, *Mardivirus*; I, *Iltovirus*. *Betaherpesvirinae*: C, *Cytomegalovirus*; M, *Muromegalovirus*; R, *Roseolovirus*; P, *Proboscivirus*. *Gammaherpesvirinae*: L, *Lymphocryptovirus*; R, *Rhadinovirus*; M, *Macavirus*; P, *Percavirus*. *Alloherpesviridae*: Ba, *Batrachovirus*; Cy, *Cyprinivirus*; Ic, *Ictalurivirus*; Sa, *Salmonivirus*. *Malacoherpessviridae*: Os, *Ostreavirus*.

Viruses that have not been approved as species are not italicized. Formally unassigned species and viruses are indicated by U and the subfamily (if known). Unofficial provisional assignments made by the authors are indicated by u.

^eGenome lengths are fuzzy for some viruses; unique segment lengths are sometimes known, and often the unit length of TR, but not TR copy number.

^fAccession numbers are provided for a clinical isolate of HCMV (Merlin) and widely studied laboratory strain (AD169), respectively.

^gValues obtained in different laboratories may reflect differences in strains.

^hComposition and length data are for the long unique segment, not including terminal repeats.

some viruses do not cause a specific disease, some viruses cause multiple and quite different diseases, and other viruses cause diseases whose etiologies are comprised of multiple agents. The formal nomenclature scheme was not meant to supplant the informal names that have been grandfathered by time and usage. The intent was to create an orderly system in which each virus would be named unambiguously and independently of classification or properties, which at that time were largely unknown. An important, and sometimes misunderstood, extension of this is that the species number is not intended to imply anything about the relationship between a virus and other herpesviruses that infect the same host species (e.g., HHV-7 and HHV-8 are members of different subfamilies) or between similarly num-

bered viruses that infect different host species (e.g., EHV-2 and BoHV-2 are members of different subfamilies).

Classification

In the late 1970s, before viral DNA and amino acid sequences were known, herpesviruses were initially classified into one family (the *Herpesviridae*) and three subfamilies (the *Alphaherpesvirinae*, the *Betaherpesvirinae*, and the *Gammaherpesvirinae*) on the basis of biological properties.¹⁰⁷ Remarkably, this framework remains useful and is supported by a deep and growing body of information extracted from nucleotide sequences. The viruses have been further classified into genera based on DNA sequence similarity, similarities in genome sequence

TABLE 59.2 Genes Conserved among the Alpha-, Beta-, and Gammaherpesviruses

Function ^a	HSV Homolog	Gene Block ^b	Function ^a	HSV Homolog	Gene Block ^b
Gene Regulation			<i>Capsid</i>		
Multifunctional regulator of expression (MRE)	UL54	3	Major capsid protein (pentons and hexons; MCP)	UL19	5
Nucleotide Metabolism			Portal protein (PORT)	UL6	6
Ribonucleotide reductase, large subunit (RR1)	UL39	1	Portal capping protein (PCP)	UL25	4
Uracil-DNA glycosylase (UNG)	UL2	7	Capsid triplex monomer (TRI1)	UL38	1
Deoxyuridine triphosphatase (dUTPase)	UL50	3	dimer (TRI2)	UL18	5
DNA Replication			Small capsid protein (SCP) at hexon tips	UL35	1
Helicase/primase complex			<i>Tegument</i>		
ATPase subunit (HP1)	UL5	6	Encapsidation and egress protein (EEP)	UL7	6
RNA pol subunit (HP2)	UL52	3	Myristoylated/palmitoylated cytoplasmic egress tegument protein (CETP)	UL11	6
Subunit C (HP3)	UL8	6	Virion protein kinase (VPK)	UL13	6
DNA polymerase (POL)	UL30	2	Encapsidation chaperone protein (ECP)	UL14	6
ssDNA binding (SSB)	UL29	2	CETP binding protein (CETPbp)	UL16	6
DNA polymerase processivity subunit (PPS)	UL42	1	Capsid transport tegument protein (CTTP)	UL17	6
Virion			Cytoplasmic egress facilitator 2 (CEF2)	UL21	5
<i>Nonstructural; roles in virion maturation</i>			Cell-to-cell fusion inhibitor	UL24	4
Alkaline exonuclease (NUC)	UL12	6	Large tegument protein (LTP)	UL36	1
Capsid transport nuclear protein (CTNP)	UL32	1	LTP binding protein (LTPbp)	UL37	1
Terminase binding protein (TERbp)	UL33	1	Cytoplasmic egress facilitator 1 (CEF1)	UL51	3
Terminase (TER)			<i>Envelope</i>		
TER ATPase subunit (TER1)	UL15	6	Glycoprotein B (gB)	UL27	2
TER DNA recognition subunit (TER2)	UL28	2	Glycoprotein H (gH)	UL22	4
Assembly protease (PR)	UL26	4	Glycoprotein L (gL)	UL1	7
Assembly protein precursor (pAP)	UL26.5	4	Glycoprotein M (gM)	UL10	6
Capsid nuclear egress complex			Glycoprotein N (gN)	UL49.5	3
Nuclear egress membrane protein (NEMP)	UL34	1			
Nuclear egress lamina protein (NELP)	UL31	1			

^aNomenclature and abbreviations are as described and proposed in.⁸⁴

^bGene blocks are as illustrated in Figure 59.5.

arrangement, and immunologic relatedness of important viral proteins.

There has been an explosion of herpesviruses discovered through the use of degenerate polymerase chain reaction (PCR) primers that target highly conserved regions in core genes, such as the DNA polymerase.¹¹⁰ Most of this work has been done by assaying blood specimens, thus the list of known lymphotropic gammaherpesviruses has expanded greatly and additional beta-herpesviruses have been identified. Expansion of the hunt to somewhat more difficult to obtain materials such as saliva or throat swabs and ganglia will likely yield a new array of novel viruses, including alphaherpesviruses. These new observations are important in that they thus far affirm the long-held hypothesis that individual animal species, or groups of closely related species, are hosts to particular herpesvirus species, with mammalian hosts being inhabited by viruses that represent each of the major mammalian herpesvirus lineages. Although the PCR

amplimers sequenced in many of these studies are less than 400 base pairs (bp) long, the information is usually sufficient for reliable assignment of the novel virus to an established subfamily; genus-level assignments are less reliable in the absence of more extensive information.

Alphaherpesvirinae

This subfamily is defined on the basis of a variable host range, relatively short reproductive cycle, rapid spread in culture, efficient destruction of infected cells, and capacity to establish latent infections primarily—but not exclusively—in sensory ganglia. This subfamily contains the genera *Mardivirus* (GaHV-2), *Iltovirus* (GaHV-1), *Simplexvirus* (HSV-1), and *Varicellovirus* (VZV). *Simplexviruses* and *Varicelloviruses* have mammalian hosts, while *Mardiviruses* and *Iltoviruses* have avian hosts. Reptilian herpesviruses belong to the alphaherpesvirus lineage, but do not belong to any of the currently designated genera.⁷⁶

Betaherpesvirinae

A nonexclusive characteristic of the members of this subfamily is a restricted host range. The reproductive cycle can be long (over 7 days), and the infection progresses slowly in cultured cells. Infected cells frequently become enlarged (cytomegalia), and carrier cultures are readily established. Betaherpesviruses can establish latency in secretory glands, lymphoreticular cells, kidneys, and other tissues. This subfamily contains the genera *Cytomegalovirus* (HCMV), *Muromegalovirus* (MCMV), *Proboscivirus* (EIHV-1), and *Roseolovirus* (HHV-6).

Gammaherpesvirinae

The host range of the members of this subfamily is restricted to the family or order of the natural host. *In vitro* all members replicate in lymphoblastoid cells, and some can lytically infect particular types of epithelioid and fibroblastic cells. Viruses in this group are usually specific for either T or B lymphocytes. Latency is ordinarily established in lymphoid tissue. This subfamily currently contains four genera: *Lymphocryptovirus* (EBV), *Macavirus* (AIHV-1), *Percavirus* (EHV-2), and *Rhadinovirus* (KSHV). Rhadinoviruses are mainly hosted by primates, Macaviruses are related to the malignant catarrhal fever viruses of ruminants, and the identified Percaviruses are hosted by perissodactyl and carnivore species. The lymphocryptoviruses consist of two major lineages that appear to have co-evolved with their hosts: viruses of Old World (humans, chimpanzees) and New World (marmosets) primates.^{43,77}

VIRION ARCHITECTURE

The Virion

Mature herpesvirus virions vary in size from 120 to as much as 260 nm (reviewed in 109). The variation is in part due to variability in the thickness of tegument. Another major source of observed variability is the state of the envelope. Intact envelopes are impermeable and generally retain the quasispherical shape of the virion during preparation for electron microscopy (Fig. 59.1). Damaged envelopes are permeable to negative stains and the virions lose their quasispherical shape; permeated virions spread out on solid surfaces, resulting in a sunny-side-up egg appearance with a diameter much larger than for intact virions. The precise number of protein species contained in the virions is not known and may vary from one virus to another. Estimates based on analysis of purified virions in protein gels have generally been in the range of 35 to 45 major species. Proteomic analyses have identified from 24 to 71 virally encoded proteins in virions (4–7 in the nucleocapsid, 9–>20 in the tegument, and 4–19 in the envelope, plus a number of proteins whose location within virions is unknown).^{56,59,82,98,126} These and other studies also identified a number of host proteins in virion preparations, including moderately abundant quantities of cellular structural proteins, enzymes, and chaperones; actins and annexins have been consistently identified. The roles and necessity of the host-derived proteins in infection are not known. The abundance of individual protein species varies widely, from less than one copy per virion to over 1,000. Individual virions harbor on the order of 10,000 individual protein molecules. In addition to proteins, virions can include viral- and cellular-encoded messenger RNAs (mRNAs) that can be translated immediately after infection.^{11,114}

While a lot is known about the average composition of populations of virions, the molecular definition of what constitutes an infectious virion remains to be defined. For example, gB is present in virion preparations at levels that correspond to an average of approximately 800 copies per virion. It is not known how widely the number of copies per virion ranges, or how many copies of gB are required to be present on a virion for it to be infectious. Importantly, most of the virus particles released from infected cells are not competent for virus replication but are bioactive in various ways. These include particles that appear by electron microscopy to be intact and complete virions of the sort just described. In addition, herpesviruses can produce large numbers of nonvirion particles of unknown biological significance, such as the dense bodies of HCMV, which are capsid-free, enveloped collections of tegument proteins.

Virion Components

The Core

The core of the mature virion contains a single molecule of the viral genome, in the form of nonchromatinized dsDNA that is packed in an orderly manner in the form of a torus.^{40,41,64,93,138} In some herpesvirions, the torus appears to be suspended by a proteinaceous spindle consisting of fibrils embedded in the underside of the capsid and passing through the hole of the torus. The precise arrangement of the DNA in the torus is not known, but the DNA is packed tightly, such that the internal volume of the capsid is approximately equal to the cylindrical volume of the genome. Because of the repulsive forces generated by the negatively charged phosphates that make up the backbone of the genome, such compact packing necessitates the abundant presence in the core of the anion spermine.⁴⁵ Packaging of the viral genome into the capsid core requires ATP and results in a pressurized system that appears to be important for injection of virus genomes through the nuclear pore complex into nuclei of newly infected cells.⁶³

The Capsid

The structural features of the capsid—that is, its 100-nm diameter, 161 capsomeres (150 hexons and 11 pentons), portal complex, and capsid triangulation number ($T = 16$)—are characteristic of all herpesviruses, including the distantly related fish and oyster viruses.^{9,31,64} Nonenveloped capsids are present in infected cells in three main forms: A-, B-, and C-capsids.⁴⁴ A-capsids have no core structure, B-capsids contain the assembly scaffold but no genome, and C-capsids are DNA-containing species that no longer house the scaffold. The four conserved capsid proteins that comprise the major structural features of the capsid include the major capsid protein (MCP), the monomer and dimer proteins of the triplex (TRI1 and TRI2, respectively), and the small capsomere-interacting protein (SCP; HSV homologs are listed in Table 59.2). MCP is present in six copies per hexon ($6 \times 150 = 900$ copies per capsid) and five per penton ($5 \times 11 = 55$ copies per capsid), for a total of 955 copies per capsid. The triplex proteins interact with $\alpha\beta$ stoichiometry and form complexes that are present at the 320 sites of threefold symmetry. Hexameric capsomeres are 9.5×12.5 nm in longitudinal section; a channel of 4 nm in diameter runs from the surface along their long axis.¹³³ Penton channels are generally somewhat narrower and are nearly closed at their midpoint in B-capsids.¹³⁵ The twelfth pentonal position is the portal for transit of genomic

DNA into and out of the capsid; it is composed of 12 copies of the capsid portal protein (PORT). The portal capping protein (PCP) is associated with mature, DNA-containing nucleocapsids. Cryoelectron microscopic image analysis has enabled reconstruction of capsid structures to greater than 10 Å resolution.¹³⁹ Among other things, this has revealed a unique protein fold in the herpesvirus major capsid protein that is shared with the capsid proteins of tailed DNA bacteriophages, in support of a primordial linkage between these viruses.⁷ Beautiful animated representations of herpesvirus capsids and capsid components are available at <http://www.eicn.ucla.edu/animations>.

The Tegument

The tegument, a term introduced by Roizman and Furlong¹⁰⁹ to describe the proteinaceous structure between the nucleocapsid and the envelope, has no distinctive features in thin sections but may appear to be fibrous on negative staining.^{90,91,133} The tegument is sometimes distributed asymmetrically, and its thickness may vary, depending on the location of the virion within the infected cell. When the amount is variable, there is more of it in virions accumulating in cytoplasmic vacuoles than in those accumulating in the perinuclear space.⁴⁰ Some evidence suggests that the amount of tegument is more determined by the virus than by the host.⁷¹ Teguments can contain more than 20 different virally encoded proteins, some of which are present at hundreds of copies per virion. Structural polarity across the tegument has been visualized by immunoelectron microscopy,¹²⁰ indicating that it is an ordered structure, an observation supported by cryoelectron microscopic observations of tegument–nucleocapsid interactions.^{123,134} This is further evidenced by tegument proteins that are closely associated with the nucleocapsid (inner tegument) being acquired in the nucleus and by interactions between envelope glycoproteins and tegument proteins at the tegument periphery. Following nuclear egress, subsequent components of the tegument are likely added in a somewhat ordered manner as the virus particle matures during its trek through the cytoplasm.⁸⁰ One purpose of the tegument is to carry into newly infected cells an assortment, or toolbox, of already synthesized proteins that can immediately begin to manage the host environment to meet the needs of the virus, such as by shutting down host protein synthesis, inhibiting infection-triggered cell defenses, and stimulating viral gene expression.

The Envelope

Electron microscopic studies on thin sections have shown that the outer covering of the virion, the envelope, has a typical trilaminar appearance.³⁸ The presence of lipids was demonstrated by analyses of virions⁵ and by the sensitivity of the virions to lipid solvents and detergents.¹¹⁸ Virion envelopes are derived from patches of altered membrane that trace to the organelle where envelopment occurs.^{3,40,66,91} A major constituent of virion envelopes is a collection of virally encoded glycoproteins. The number and relative amounts of viral glycoproteins vary among herpesviruses. HSV specifies at least 11 different virion-associated glycoproteins, and the copy number of individual glycoproteins can exceed 1,000 per virion. The glycoproteins form numerous protrusions on virion envelopes that are more numerous and shorter than those present on the surface of many other enveloped viruses.¹³³

GENOMIC AND GENETIC ARCHITECTURE

Genome Size and Base Composition

Herpesvirus DNAs extracted from virions and characterized to date are linear and double stranded, but they circularize immediately on release from nucleocapsids into the nuclei of infected cells.

Distinguishing features of herpesvirus DNAs include their length and base composition. The length of herpesvirus DNAs varies from approximately 124 to 295 kbp (Table 59.1 and e-Table 59.2). The variability in genome lengths of different herpesviruses is distinct from the generally less extensive polymorphism in the size of DNAs of individual viruses. Thus, herpesvirus genomes contain terminal and internal reiterated sequences that can vary in copy number, as well as sequences that can be lost or duplicated during passage in cell culture, leading to intraspecies variation in genome lengths that can exceed 10 kbp.

The base composition of herpesvirus DNAs varies from 31% to 77% total G+C content (Table 59.1 and e-Table 59.2). Furthermore, herpesvirus DNAs vary with respect to the extent of homogeneity of G+C content across the length of the genome (generally higher G+C composition in terminal repeats). The extent of inhomogeneity in the base composition varies from minimal (e.g., HSV) to very extensive. For example, the genome of MuHV-4 has a G+C content of 46% in its unique region and 78% in its terminal repeats.¹³⁰

The genetic requirements for efficient replication in cultured cells can differ from the *in vivo* requirements. Spontaneous deletions have been noted in HSV and EBV strains passaged outside the human host (e.g., EBV strain P3HR1, HSV-1 strain HFEM). Highly passaged strains of HCMV lack a segment encoding at least 19 genes that are present in wild-type isolates.¹⁷ A progression of changes in a small number of genes enables clinical isolates of HCMV to begin replicating efficiently in cultured cells.²³

Sequence Arrangements

An interesting feature of herpesvirus genomes is their sequence arrangement. The sequence arrangements shown in Figure 59.4 emphasize the presence and location of reiterations of terminal sequences greater than 100 bp. According to this scheme, herpesviruses genomes can be divided into six groups designated by the letters A to F. In the genomes of viruses comprising group A and exemplified by HHV-6, a large sequence from one terminus is directly repeated at the other terminus. In the group B genomes, exemplified by herpesvirus saimiri (SaHV-2), the terminal sequence is directly repeated numerous times at both termini; furthermore, the number of reiterations at the termini may vary. In the group C genomes exemplified by EBV, the number of direct terminal reiterations is smaller. In addition, group C genomes can harbor other direct sequence arrays that subdivide the unique (or quasiunique) sequences of the genome into several well-delineated stretches. In group D genomes, exemplified by VZV, the sequence from one terminus is repeated in an inverted orientation internally. In these genomes, the domain consisting of the stretch of unique sequences flanked by inverted repeats (Small or S component) can invert relative to the remaining sequences (Large or L component) such that the DNA extracted from virions or infected cells consists of two equimolar populations differing solely in the orientation of the S component

FIGURE 59.4. Schematic diagram of the sequence arrangements in the six classes of genomes of the viruses comprising the family *Herpesviridae*. Group A, B, C, D, E, and F genomes are exemplified by the human herpesvirus 6, herpesvirus saimiri, EBV, varicella-zoster virus, herpes simplex viruses, and tupaia herpesvirus, respectively. In the schematic diagram, *horizontal lines* represent unique or quasiunique regions. The reiterated domains are shown as *rectangles* and are designated as left and right terminal repeats (LTR and RTR) for group A, repeats R1 to R4 for internal repeats of group C, and internal and terminal (IR and TR) repeats of group D. The termini of group E (e.g., HSV) consist of two elements. One terminus contains *n* copies of sequence *a* next to a larger sequence designated as *b*. The other terminus has one directly repeated *a* sequence next to a sequence designated as *c*. The terminal *ab* and *ca* sequences are inserted in an inverted orientation (denoted by primes) separating the unique sequences into long (U_L) and short (U_S) domains. Terminal reiterations in the genomes of group F have not been described. In group B, the terminal sequences are reiterated numerous times at both termini. The number of reiterations at each terminus may vary. The components of the genomes in groups D and E invert. In group D, the short component inverts relative to the long. Although the long component may also rarely invert, most of the DNA forms two populations differing in the orientation of the short component. In the group E genomes, both the short and long components can invert, and viral DNA consists of four equimolar isomers.

relative to the L component. In group E viral genomes, exemplified by HSV and HCMV, sequences from both termini are repeated in an inverted orientation and juxtaposed internally, dividing the genomes into two components, each of which consists of unique sequences flanked by unrelated pairs of inverted repeats. In this instance, both components can invert relative to each other, and DNA extracted from virions or infected cells consists of four equimolar populations of isomers that differ in the relative orientation of the two components. The genomes comprising group F are exemplified by tupaia herpesvirus 1 (TuHV-1); the terminal sequences are not identical and are not repeated either directly or in an inverted orientation. Although the potential of inverted repeat sequences to cause inversions and gene expansion is well appreciated, their role and the advantage they confer to viral replication are not understood.

All herpesvirus genomes examined to date contain at their termini conserved *cis*-acting signals for packaging of the DNA into capsids and cleavage of concatemeric genomes to unit length (cleavage/packaging, or *pac* sequences).³²

Genetic Architecture

Herpesvirus Genes

Most herpesvirus genes contain a collection of promoter/regulatory sequence elements that are located 50 to 200 bp

upstream of a TATA box, a transcription initiation site 20 to 25 bp downstream of the TATA box, a 5' nontranslated leader sequence of 30 to 300 bp, a single major open reading frame with a translation initiation codon that meets the host requirements for efficient initiation, 10 to 30 bp of 3' nontranslated sequence, and a canonical polyadenylation signal with standard flanking sequences (e-Fig. 59.1A). As illustrated, variation and exceptions exist and are important. Genes without a TATA box (e.g., HSV-1 γ 134.5 gene)²⁰ and initiation from a second in-frame methionine⁶⁹ have been reported. In the case of HSV late genes, the promoter-regulatory sequences may be located 3' to the TATA box.⁷⁰

Gene overlaps are common. For head-to-tail gene arrangements, the upstream gene can overlap with the promoter-regulatory sequences of the downstream gene (e-Fig. 59.1B). In several instances, a second transcriptional unit is embedded in a protein coding sequence to yield a shorter polypeptide that is initiated at an internal methionine within the same open reading frame as the larger protein (e.g., HSV UL26 and UL26.5; e-Fig. 59.1C).⁶⁵ The resulting proteins thus share a domain of identical amino acid sequence, yet can differ markedly in their function. Protein-encoding open reading frames can be expressed from mRNAs that are antisense to each other (e.g., HSV-1 γ 134.5 and ORF P and O; e-Fig. 59.1D).⁶² Common features of herpesvirus genomes are clusters of 3' co-terminal transcripts, each designed to express a different open reading frame (e-Fig. 59.1B). Within these clusters, coding domains seldom overlap by more than a few codons. Although most genes are transcribed by RNA polymerase II; some small transcripts are transcribed by RNA polymerase III, for example, the EBV EBER transcripts.⁵²

The predominant form of transcript for most herpesvirus genes is unspliced; that is, the primary transcription product only needs to be polyadenylated to form the mature mRNA. The number of genes for which the predominant transcript is spliced varies from very few for some herpesviruses to about 10%. One strategy is to use splicing to enable differential regulation of a gene at different parts of the virus life cycle. In some cases, this means the same open reading frame can be accessed from different promoters. Differential splice-site selection can be used to express different open reading frames from the same primary transcript (e-Fig. 59.1E). Recent application of deep sequencing to transcript analysis demonstrated that RNA splicing (including alternative splicing) is more common than previously recognized.⁴² Herpesviruses also encode noncoding RNAs, some of which are highly abundant, e.g., the Ori_S RNA and latency-associated transcripts of HSV, the EBERs of EBV, and microRNAs.^{104,115,121}

Genomes of members of the *Herpesviridae* encode between 70 (the smallest genome) and 200 (the largest genome) protein-coding genes. These estimates are rooted in studies of viral mutants, transcriptional mapping, analysis of the translation products of particular transcripts, and computational analyses of protein-coding potential. Current estimates probably understate the number of gene products. Noncoding RNAs are not included in these counts, nor are very small open reading frames that have not been identified as functional. Functions that arise as products of alternative splicing, translational frame shifting, internal translation initiation sites, antisense open reading frames, and tissue-specific transcription are only beginning to be fully appreciated. Elucidation of the true genetic

and corresponding functional complexity encoded in herpesvirus genomes remains a major objective of herpesvirus research.

Naming of Genes and Their Products

ICTV has established a framework for naming of herpesviruses, but there is no formal system for naming viral genes or their products. This has led to several problems that can be particularly daunting to newcomers to the field: the nomenclature applied to viral genes and their products is a hodgepodge, difficult to follow, and potentially misleading. Historical precedents, self-interests, and common usage maintain nomenclatures whose time has long passed. The nature of the problems facing us can be summarized with a few examples.

The HSV-1 virion transactivator was first identified as a component of the virion and designated by its migration in denaturing gels relative to that of other virion proteins (VP16).¹¹⁷ Subsequently, it was designated by its migration in denaturing gels relative to other infected cell proteins (ICP25).⁵¹ Still later it was designated by its apparent molecular weight in denaturing polyacrylamide gels (vmw65),¹⁶ its best known function (α -trans-inducing factor or α -TIF),¹⁰³ or by the position of the gene encoding it (UL48).⁷⁴ Another example is the major regulatory protein of HSV-1, which was designated initially as ICP4 and subsequently as vmw175 and α 4.

HSV is not the only herpesvirus beset by problems in nomenclature of its genes and proteins. For example, with the exceptions of the proteins expressed during latent infection, EBV genes and their products are named after a restriction endonuclease-generated DNA fragment in which the gene maps. This nomenclature precludes all but the most dedicated from visualizing the position of the gene.

The least precise current designations are based on apparent molecular weight. For example, ICP4 (vmw175) is expressed in several forms that differ in electrophoretic mobility in denaturing polyacrylamide gels. In addition, the apparent molecular weights relative to standards may vary, depending on the composition of the gel. Furthermore, although the HSV-2 homolog has a higher apparent molecular weight, it is sometimes designated by the apparent molecular weight of its HSV-1 counterpart.

The naming of homologous genes based on their HSV-1 counterparts enables a relational database but leads to a loss of information and may be misleading. For example, glycoprotein B is encoded as HSV UL28, HHV-6B U39, HCMV UL55, KSHV orf8, and so on. A designation such as gB (HHV-6B) addresses sequence homology but not map position. An additional hazard is the assumption that all functions of orthologous gene products are fully conserved from virus to virus. Most herpesvirus proteins studied in detail have multiple functions; proteins sharing a conserved block of amino acids may diverge in the functions encoded in their other domains; future nomenclatures may need to account for the multifunctionality of viral proteins. Ideally, protein names would convey key information useful to the field, such as major function, kinetic class, and genome map location.

What is being done? Gene name cross-references are often available in papers that describe complete herpesvirus genome sequences (e.g., 2,6,46,95), as well as in freely available compendia.^{67,83,84,106b} The unified nomenclature and abbreviation system proposed for genes conserved across the *Herpesviridae*⁸⁴ is used in this chapter. In addition, a more highly curated set of reference herpesvirus genome sequences has been compiled at

Genbank (<http://www.ncbi.nlm.nih.gov/genomes/VIRUSES/viruses.html>). These sequences have an accession number with an "NC_" prefix and are listed in Table 59.1 and e-Table 59.2. Reference sequences are derived from the original sequence submissions, but are maintained and curated separately to ensure a degree of uniformity in describing gene boundaries and names.

Gene Functions

The viral functome is the net functional manifestation of the viral genome, transcriptome, and proteome. A challenge in fully defining the viral functome is the fact that no experimental system can fully mimic the biology of the natural host. A variety of methods have been developed to enable genetic studies of herpesviruses. A widely used approach involves cloning complete herpesvirus genomes into plasmids that can replicate in *E. coli* as bacterial artificial chromosomes (BAC).^{131,137} This allows the use of powerful and specific mutagenesis methods, followed by transfection of the mutagenized genome into susceptible mammalian cells where the virus can be regenerated.

Two key characteristics define the functionality of herpesvirus gene products. First, they frequently have multiple functions that may or may not be related. For example, HSV-infected cell protein 0 (ICP 0 or α 0) is a promiscuous transactivator, but at a molecular level it first localizes sequentially in the nucleus and later in the cytoplasm, and interacts with several host proteins located in both compartments.^{39,60} Even some of the smaller proteins (e.g., HSV-1 US11 and γ 134.5) have been ascribed more than one function. The decision as to which function is performed by a particular protein may be determined by the nature of posttranslational modifications to which many herpesvirus proteins are subjected. Full assessment of the multifunctional nature of viral proteins and their dependence on interactions with other viral proteins requires that they be studied in the context of infection.

The second key characteristic relates to the role of virus-encoded proteins in viral replication. For HSV, more than 50% of the open reading frames are dispensable for growth in cells in culture. For the most part, however, these genes are not dispensable for viral replication or for reactivation from the latent state in experimental animal systems. In contrast, in assays involving establishment of latency, no virus gene has been found to be indispensable. Genes that are necessary for virus replication in cultured cells are sometimes referred to as "essential" or "fundamental," and dispensable genes as "nonessential" or "accessory."

Virally encoded proteins are required for entry into the cell, regulation of viral gene expression, nucleotide metabolism, synthesis of viral DNA, structural proteins, and virion assembly, as well as for management of host defenses, metabolism, and macromolecular biosynthesis and transport. Regulatory genes are specifically adapted to the requirements of the cell type inhabited by the virus *in vivo*. Some subsets of herpesviruses (e.g., the alphaherpesviruses) share clear homologs of regulatory genes such as α 4, α 0, and α 27. Other groups of herpesviruses have important regulatory genes that have little obvious sequence similarity, although they may occupy similar genomic locations and even share splicing patterns (e.g., the immediately early genes of the betaherpesviruses).

Every herpesvirus studied to date establishes latent infection in a specific population of cells. The mechanisms differ from one virus to the next. There appears to be no general strategy or shared genetic component for establishment, maintenance, or

termination of the latent state, even though latency is the cornerstone of herpesvirus biology. Although members of some genera of herpesviruses encode several proteins that are expressed during maintenance of the latent state (e.g., EBV), others (e.g., HSV) have no absolutely required expression of the viral genome during this phase of latency.

The cellular and organismal host ranges of herpesviruses differ enormously, from very wide (e.g., HSV) to very narrow (e.g., EBV, HHV-6B). The host range is determined only in part by the availability of receptors. Little is known about the virus- and cell-specific factors that enable herpesviruses to replicate in specific hosts or cell types.

Herpesviruses are able to alter the cellular environment to suit their needs. These alterations include shutting off or stimulating host-cell macromolecular synthesis, inducing or inhibiting host-cell DNA replication, or immortalizing the host cell. Many viral genes have been identified as specific regulators of these processes; this remains an area of active research.

The environment in which herpesviruses replicate is decidedly unfriendly to the virus. An armamentarium of viral functions is encoded by herpesviruses to fend off cellular and organismal reactions to the presence and expression of viral genes (reviewed in 8,27,85,86). At the cellular level, the virus blocks the induction of programmed cell death and the activation of the interferon pathway (e.g., by activation of protein kinase R). At the organismal level, the response is highly varied and depends in part on the cells in which the virus replicates. Here the responses range from blocking the presentation of antigenic peptides on the surfaces of antigenic cells to molecular mimicry, in which herpesvirus-encoded proteins perform some, but not all, functions of immunomodulators. A common consequence is a delay in the elimination of the infected cell—long enough to enable the virus to replicate, colonize the host, and become available for transmission to another nonimmune individual. The range of genes evolved to this end varies from one genus to another, with limited conservation among members of subfamilies. Alphaherpesviruses have adopted a different general strategy for accomplishing this than the beta- and gammaherpesviruses, in that the former sequesters cellular proteins and modifies them to perform novel functions (e.g., HSV-1 $\gamma_{134.5}$ and the cellular protein phosphatase 1 α). Beta- and gammaherpesviruses encode numerous orthologs of cellular proteins designed to mislead the cell or directly perform the desired function (often with altered regulatory properties). Herpesviruses have evolved multiple ways in which to attain the same objectives: for example, the many ways they block the action of interferon or block the attempt of infected cells to commit suicide (apoptosis). The diversity of approaches is a remarkable testimony both to the depth and complexity of host defenses and to the adaptive prowess of the virus. That the virus wins in the infected cell but normally allows the host to survive attests to an evolutionary necessity.

Regulation of Gene Expression

Herpesvirus genes belong to one of several regulatory classes; the more they are studied, the more complex the systems that regulate their expression appear to be. Standing apart are genes expressed during latency, and even here, as in the case of EBV, there are multiple forms of latency differing with respect to the genes that are expressed. Herpesvirus gene expression during productive infection represents a classic regulatory cascade,

the basic features of which are conserved across the family. In productively infected cells, viral genes form at least four groups differing with respect to the order of gene expression and the mechanisms that drive it. These are the α (immediate-early) genes that require no new (cellular or viral) protein synthesis for their expression, β (early) genes whose transcription is totally independent of viral DNA synthesis, γ_1 (leaky-late) genes whose expression is augmented by the onset of viral DNA synthesis, and γ_2 (true late) genes whose expression is totally dependent on viral DNA synthesis. The immediate-early, early, and late nomenclature is rooted in early phage studies; it has the virtue of instant recognition but does not fully describe the events occurring in the infected cell. Both systems are used widely and interchangeably.

As mentioned, most herpesvirus genes are transcribed by the host RNA polymerase II, as regulated by numerous viral and cellular proteins. An important aspect of transcriptional regulation relates to the state of chromatinization of the viral genome, which is dynamically regulated in a virus- and cell-specific manner from the time the viral genome is injected into the nucleus at the initiation of infection, and then throughout the processes of lytic replication and establishment, maintenance, and reactivation of latent infections. Transcriptional expression of herpesvirus genes during lytic infection thus appears to be regulated by sequential derepression of viral genes that were repressed by the host at the moment of viral DNA entry into the nucleus. At least for HSV-1, the initial stages of virus gene transcription during reactivation from neuronal latency can be disordered with respect to viral gene classes. This suggests that reactivation can involve a general, rather than targeted, derepression of viral gene expression.³³

Gene Relatedness and Arrangement

Complete genomic sequences have been determined for more than 50 herpesviruses (Table 59.1 and e-Table 59.2); smaller segments have been sequenced from many others. From this information, several fundamental principles of herpesvirus genetic architecture have been deduced.

Herpesvirus gene sequences are related to each other in ways that reflect the long-standing, biology-based classification of herpesviruses into subfamilies and their respective genera, as described here. These relationships are substantial and easy to detect with any of the widely available tools for sequence analysis. As mentioned, for viruses of the *Herpesviridae*, the nucleotide sequence of a 400-bp PCR product amplified from the viral DNA polymerase gene by the use of degenerate consensus primers is sufficient to establish the identity of a herpesvirus and place it into the appropriate subfamily. Higher resolution and more robust classification can be obtained by expanding the size of the comparison sequence and by analyzing more than one gene. Phylogenetic trees topologically similar to those obtained by comparing amino acid sequences have been obtained from comparisons based on which members of conserved sets of genes are represented in a given lineage or virus species.^{1,87} A representation of herpesvirus taxonomic and phylogenetic relationships is shown in Figure 59.2.

Forty-one genes, referred to as the herpesvirus core genes, have been identified as conserved across the alpha-, beta-, and gammaherpesviruses (Table 59.2). Each gene belongs to one of six core gene blocks. Within each gene block, gene order and polarity are conserved (Fig. 59.5). Across the family, the

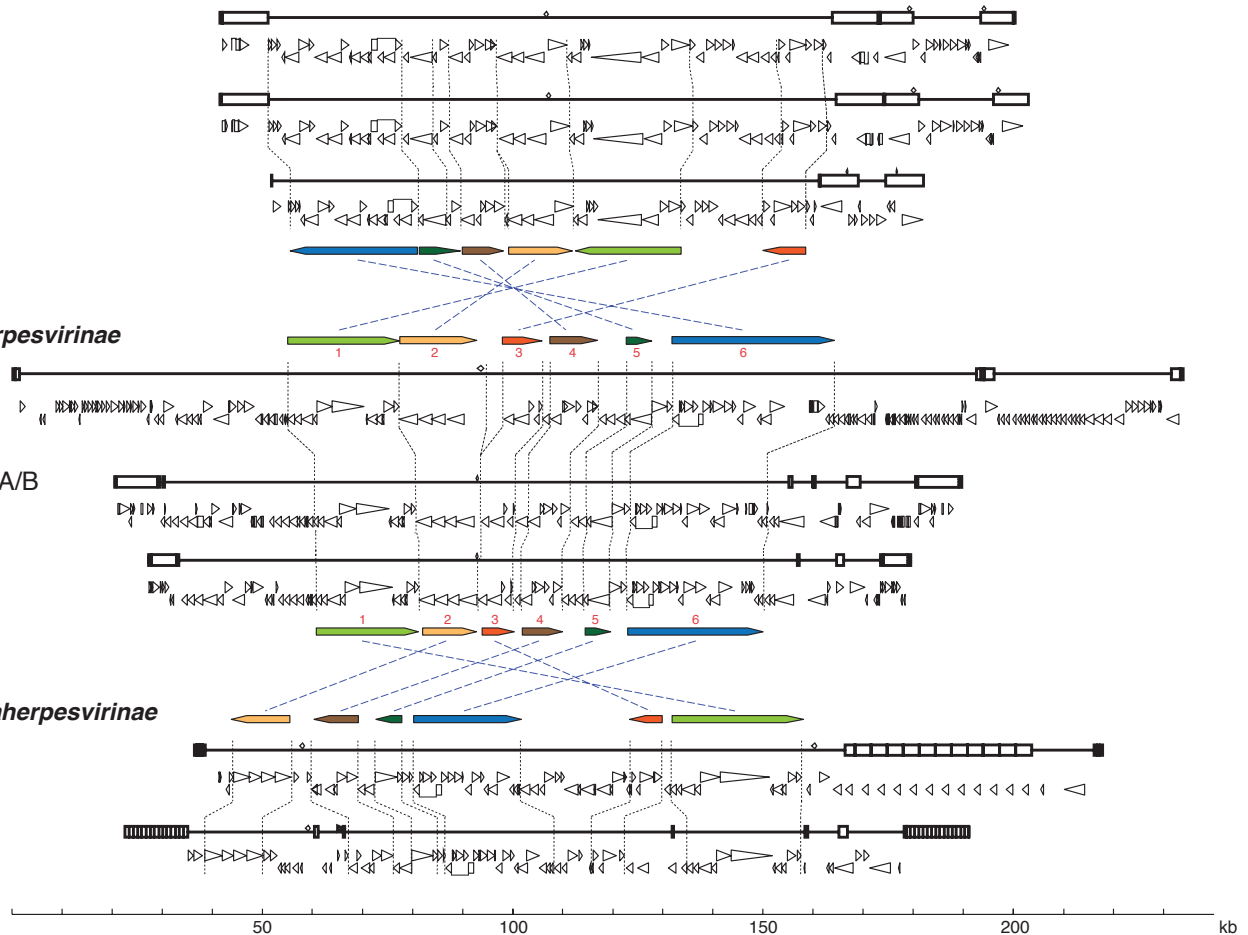

FIGURE 59.5. Genomic and genetic architectures of the human herpesviruses. Major repeat elements are indicated on each genomic schematic as *boxes*. Beneath each genome, open reading frames considered likely to encode expressed proteins are indicated as *triangles* that are oriented to show their direction of transcription. 5' exons of spliced genes are indicated as *boxes* that are connected by *bars* to 3' exons. The seven conserved herpesvirus sequence blocks (block 1 through block 7) are diagrammed to show their relative locations and orientations in the three major lineages. Diagrams are based on annotations and coordinates in Genbank accession numbers X14112 (HSV-1 strain 17), Z86099 (HSV-2 strain HG52), X04370 (VZV strain Dumas), NC_006273 (HCMV strain Merlin), X83413 (HHV-6A strain U1102), AF157706 (HHV-6B strain Z29), U43400 and AF037218 (HHV-7 strains JI and RK, respectively), NC_007605 (EBV strain B95-8), and U75698 (HHV-8 BC-1). Detailed descriptions are available in virus-specific chapters that follow. TRL, long component terminal repeat; IRL, long component internal repeat (inverted relative to TRL); IRS, short component internal repeat; TRS, short component terminal repeat (inverted relative to IRS); DRL and DRR, left and right direct repeats, respectively; TR, terminal direct repeat; IR, internal direct repeat. Abbreviations for conserved proteins are as listed in Table 59.2. A large format version of this diagram is available as [e-Fig 59.2](#).

core gene blocks are found in various permutations of order and orientation.^{18,30} Block arrangement, and thus gene order, is conserved at the subfamily level. As illustrated in Figure 59.6, conserved genes do not share identical sequences. In some instances, homologs share low-level sequence identity or similarity across their full lengths, while in other instances only a small portion is identifiably conserved. The implication is that the resulting proteins are an amalgam of conserved and diverged functions.

Some genes are conserved at the subfamily level. Thus, genes unique to alphaherpesviruses include their latency-associated genes, glycoprotein D, a tegument-associated protein that induces transcription from α -genes, and a transcriptional

regulatory protein related to HSV $\alpha 4$ (Fig. 59.6). Betaherpesviruses encode a block of 14 genes that have no counterparts elsewhere in the family; sets of diversified genes that are related to HCMV US22, and highly divergent immediate-early genes that nonetheless have shared evolutionary history. Gammaherpesviruses uniquely encode conserved proteins needed to maintain latent genomes in dividing cells.

An interesting variation on the linkage of gene sets to subfamilies is offered by the origin-binding protein (OBP) and its binding site. OBP binds to its cognate sites in origins of lytic replication and serves to nucleate the DNA replication machinery and play a role in initiating DNA replication. Only alphaherpesviruses and members of the *Roseolovirus* genus of

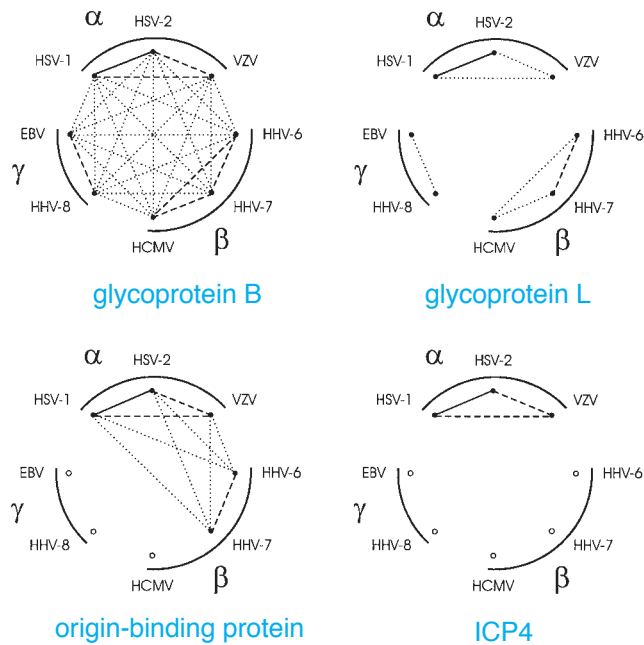

FIGURE 59.6. Patterns of gene conservation among the human herpesviruses. Viruses encoding the protein are indicated by the filled dots; empty dots indicate viruses that do not encode the protein. Degrees of similarity are indicated by the lines connecting the viruses; solid, dashed, and dotted lines represent >70%, 40% to 70%, and <40% identity, respectively. Glycoprotein B is highly conserved and is represented in all of the viruses; glycoprotein L is conserved within subfamilies; the origin-binding protein is conserved among the alpha-herpesviruses and a subset of beta-herpesviruses; ICP4 is found only in the alpha-herpesviruses. The HHV-6A and HHV-6B counterparts of these proteins are highly related to each other and have similar distances to the other viruses, thus they are represented here as a single entity.

the betaherpesviruses encode OBP homologs and OBP binding sites⁵⁴ (Fig. 59.6). Other betaherpesviruses and the gamma-herpesviruses do not encode OBP homologs or binding sites, and initiate DNA replication by another mechanism.

Herpesviruses generally encode at least one gene of obvious host origin (reviewed in 53,106); KSHV has acquired at least 12.¹¹¹ Examples include thymidylate synthase and *bcl-2*. These genes appear to have been acquired by retrotransposition events from cDNAs, given that they are most often encoded on the viral genome as continuous open reading frames that do not require splicing. Some of these genes appear to have been acquired independently by different herpesvirus lineages (again, *bcl-2* and thymidylate synthetase). Host-acquired genes tend to be located toward the viral genomic termini and between core gene blocks. In some cases, the host-acquired genes retain a function similar to its cellular counterpart; expression from the viral genome allows the desired product to be produced when needed by the virus. In other cases, the host-acquired gene has been modified to alter its function. For example, the KSHV homolog of the cellular D-type cyclin does not respond to signals that inhibit the cellular version, rendering the viral version constitutively active and capable of transforming cells.⁴

BIOLOGICAL CYCLE OF HERPESVIRUSES

The herpesvirus biological cycle can be divided into three major components: initiation of infection, lytic replication, and latency (Fig. 59.7). These components are linked by a biological decision in the infected cell to follow either the lytic or latent pathway, as well as by the ability of latently infected cells to be reactivated to a lytic state. Here we provide a general outline of the herpesvirus biological cycle; detailed descriptions of the diverse mechanisms employed by the various viruses to accomplish this are provided in subsequent chapters. It is important to

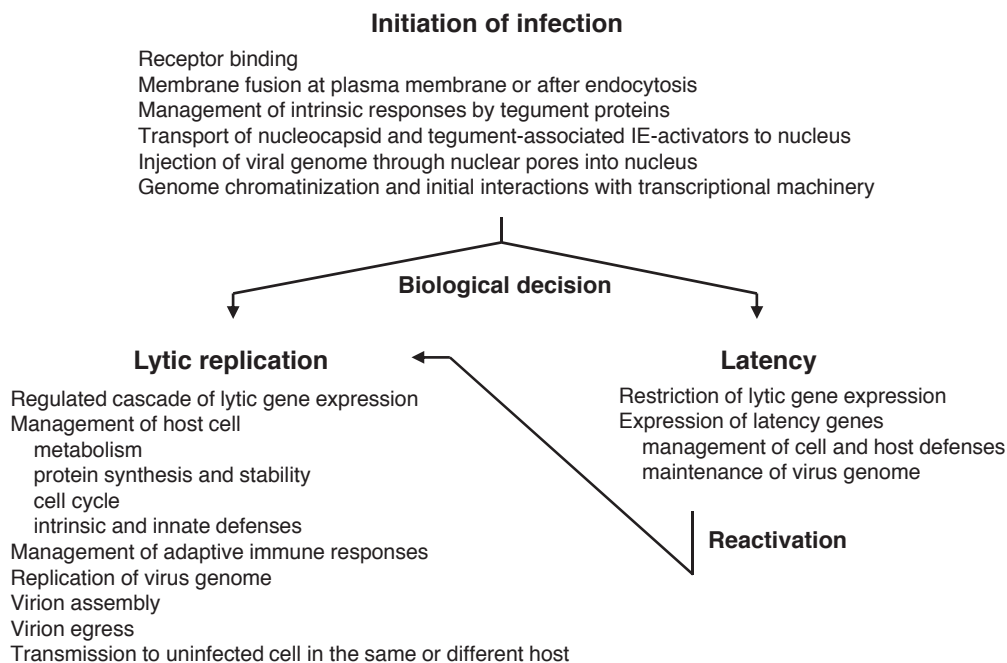

FIGURE 59.7. Herpesvirus biological cycle.

bear in mind that essentially every step and stage of the herpesvirus biological cycle is dependent on the virus making use of or adapting for its purposes cellular systems, structures, and materials. Host interactions include modification of cellular systems for regulating gene expression (transcription, mRNA processing and transport, RNA stability, translation, posttranslational processing, management of protein lifetimes), modulation of the cell cycle (e.g., to drive it to particular stages to ensure that necessary replicative precursors are available as needed), reprogramming metabolic pathways for energy production and generation of biosynthetic precursors, remodeling of the secretory apparatus, using intracellular transportation systems throughout the infectious cycle, and managing host defenses.

Initiation of Infection

Initiation of infection spans the events that begin with receptor binding through the initial interactions of the virus genome with the host transcriptional machinery in the nucleus (e-Fig. 59.3A). The general features of this stage occur in cells destined for immediate entry into the lytic state, as well as in cells that will become latently infected.

Because they infect wide varieties of cell types, individual herpesviruses employ multiple cell surface receptors for virion entry. These interactions are mediated by individual, or combinations of, virion surface virus glycoproteins. For most, if not all herpesviruses, the initial binding of the virion to the host cell involves interactions of gB with cell surface heparan sulfate proteoglycans. After receptors are fully engaged, herpesviruses enter cells by two major pathways: fusion of the virion envelope with the plasma membrane at the cell surface, or membrane fusion after virion uptake by endocytosis. Fusion of virion and cellular membranes is mediated by gB and the gH/gL complex. gB is a Class III fusion protein that has structural features in common with membrane fusion proteins encoded by viruses as diverse as vesicular stomatitis virus and baculoviruses.⁵⁰ In addition to their roles in virion entry, virion–receptor interactions activate cellular signaling pathways, some of which the virus takes advantage of, while others need to be redirected or blunted.

As part of entry, virus particles must interact with and ultimately penetrate the cytoskeleton. Because of the macromolecular density and highly structured nature of the cytoplasm, objects the size of nucleocapsids are unable to migrate from the cell surface to the nucleus by diffusion alone. By way of interactions that ultimately link to microtubule motors, nucleocapsids hitch rides on microtubules for active transport to nuclear pores. By unknown mechanisms, nucleocapsids dock with the nuclear pore complex and then release their DNA so it is translocated into the nucleus.⁶³ Injection of the genome into the nucleus is powered in part by pressurization of the capsid during virion assembly plus active consumption of ATP during translocation of the genome through the nuclear pore complex. Almost immediately upon entry into the nucleus, the virus genome is partially or unstably chromatinized. The nature of the chromatinization and the availability and state of particular viral and cellular transcription regulators are major determinants of the biological decision to either enter the lytic replication cycle or establish a latent infection.⁹⁴ Tegument proteins that are released into the cytoplasm during entry can have effector activities in the cytoplasm or nucleus. These include management of intrinsic defense responses and transcriptional activation of α genes.

Lytic Replication

The purpose of lytic replication is to manufacture infectious virions that can infect other cells and hosts. As outlined in Fig. 59.7 and e-Fig. 59.3, lytic replication includes regulated expression of virus genes, genome replication, virion assembly, egress, and transmission, all the while managing a wide range of host activities and defenses. As with any assembly line manufacturing process, virion assembly is dependent on production of appropriate levels of the various parts, plus mechanisms to ensure their presence in the proper locations when they are needed. Coordination of events during lytic infection is regulated as a function of state of infection rather than by synchronization to a molecular clock. Lytic replication involves sophisticated use of preexisting cellular compartments such as the nucleus, cytoplasm, and cytoplasmic organelles, as well as their modification and sometimes subcompartmentalization. As studied in detail for HSV, at early times after infection, gene transcription, genome replication, and nucleocapsid assembly take place in distinct but adjacent subnuclear compartments. Later in infection these appear to merge into a single large nuclear compartment, but the underlying functional organization is likely to remain.

Expression and Activities of Lytic Genes

Regulatory properties of herpesvirus gene classes were described earlier. Regardless of whether the lytic pathway is entered directly as part of a new infection, or via reactivation from latency, a key event is triggering α gene transcription in a manner that drives the coordinated cascade of lytic gene infection. As detailed in subsequent chapters, mechanisms for regulating initiation of the lytic cascade differ from virus to virus, in different cell types, and for new versus reactivated infections.

Herpesviruses typically encode approximately five α genes, whose products perform a number of regulatory functions, including activation of β gene transcription, modulation of the cell cycle, chromatin structure, RNA transport and splicing, and blunting innate, intrinsic, and adaptive immune responses. Most β gene products are involved in virus genome replication. This includes enzymatic activities that ensure adequate pools of nucleotides for viral DNA synthesis, as well as the proteins and enzymes necessary for DNA synthesis at the replication fork. Most γ gene products are virion proteins.

Genome Replication

Replication of the virus genome is dependent on the presence of sufficient biosynthetic precursors, *cis*-acting signals in the virus genome that guide assembly of the replication complex and initiation of DNA replication, and *trans*-acting factors that replicate the virus genome in a manner that is sufficiently orderly to generate several thousand genomic copies from as few as one starting template, then efficiently encapsidate the nascent genomes. In addition to encoding enzymes involved in nucleotide metabolism, some herpesviruses (e.g., HSV) alter the flow through metabolic pathways to result in enhanced pyrimidine biosynthesis,¹²⁷ while others (e.g., HCMV) appear to manipulate the tricarboxylic acid cycle to help ensure adequate supplies of lipids that are used for other stages of replication.^{92,127,136}

Herpesvirus genomes have 1 to 3 *cis*-acting sites that can act as origins of lytic DNA replication (*oriLyt*). For alphaherpesviruses and a subset of betaherpesviruses (members of the *Roseolovirus* genus), assembly of the replication complex at

these sites is dependent on the virally encoded origin-binding protein (OBP), which binds to specific oriLyf sequences and then triggers conformational changes in the virus genome that enable assembly of the replication complex and initiation of replication. Other herpesviruses employ virally encoded DNA-binding transcription factors for oriLyf activation. Regardless of how oriLyf is activated, a set of six proteins that are conserved across the *Herpesviridae* interact to form the enzymatic complex that replicates the genome. These proteins include the viral DNA polymerase (POL) and its associated processivity subunit (PPS), a single-stranded DNA (ssDNA) binding protein (SSB), and the three components of the helicase-primase complex (HP1, HP2, and HP3). Some host proteins are involved, but their roles have not been fully defined. Other forms of replication might be involved, but rolling-circle replication appears to be the major source of new genomes. Because packaged genomes are not chromatinized, thus far undefined mechanisms are needed to either prevent chromatinization during and after viral DNA replication or to remove nucleosomes from newly replicated viral DNA prior to packaging.⁹⁴

Virion Assembly and Egress

BIOSYNTHESIS AND INTRACELLULAR DELIVERY OF VIRION COMPONENTS

Dissection of the process of virion assembly needs to account for the structure of mature infectious virions and the topological constraints imposed by cellular compartmentalization (e-Fig. 59.3C). The different stages of virion assembly occur first in the nucleus and then in the cytoplasm, with extensive use made of cellular systems for synthesis, processing, and trafficking of membrane proteins, plus nucleus-cytoplasm, intra-cytoplasmic, and vesicular transport systems. The process is dependent on coordinated delivery of virion subcomponents to appropriate subcellular addresses. We can consider virion assembly to begin with translation of mRNAs for structural genes. There is no evidence to suggest it, but it is conceivable that structural gene mRNAs are delivered to ribosomes situated to facilitate transport of their products to the intended destination. Thus, mRNAs for virion glycoproteins need to be translated by ribosomes associated with the endoplasmic reticulum (ER), to begin the trafficking through the ER, Golgi apparatus, and trans-Golgi network required for sequential maturation of nascent glycoproteins and their ultimate delivery to the organelle(s) where virions are enveloped. Proteins that form structures assembled in the nucleus must be routed to systems that enable transport through the nuclear pore complex. Tegument proteins that are assembled onto virions in the cytoplasm need to be routed to areas nucleocapsids will traverse on their way to acquiring their envelope at a cytoplasmic organelle that connects to a path of cellular egress.

ASSEMBLY AND NUCLEAR EGRESS OF THE NUCLEOCAPSID

In the nucleus, nascent capsids are assembled on temporary scaffolds, then filled with newly replicated DNA in an energy-dependent manner.^{64,81,84} In addition to the structural proteins, capsid assembly is dependent on several other viral proteins, including the assembly protein precursor (pAP), the mature assembly protein (AP), and the assembly protease (PR) that is self-excised from a precursor polypeptide (prePR) that contains PR, pAP, and AP. As DNA is being spooled into the capsid through the portal, a head-full sensing mechanism

operates, triggering cleavage of the genome at the conserved *pac* sequences that define the genomic termini. The cleavage is mediated via interactions among PORT, the heterodimeric terminase (TER1 and TER2), TER binding protein (TERbp), and the portal capping protein (PCP). Filled and capped nucleocapsids are pressurized and very rigid.

The mechanisms employed for transport of filled nucleocapsids from the nucleus are not fully understood. Three paths of nuclear egress have been considered in depth^{14,37,57,79–81}: envelopment at the inner nuclear membrane followed by subsequent cytoplasmic transport on the interior (within the lumen) of membrane-bounded tubes and vesicles such as cisternae of the rough ER and Golgi apparatus; envelopment at the inner nuclear membrane, then de-envelopment during entry to the cytoplasm; and direct transport of nonenveloped particles to the cytoplasm through enlarged nuclear pores or a disintegrated nuclear membrane (e-Fig. 59.3C).

The luminal transport model predicts that the envelope acquired at the inner nuclear membrane is the same membrane present on mature extracellular virions. Two of the major lines of evidence against this model are: some tegument and envelope proteins acquired during envelopment at the inner nuclear membrane are absent from mature virions; and most tegument proteins are acquired in the cytoplasm, not in the nucleus, and no mechanism has been postulated for addition of tegument proteins to enveloped virions.

In the envelopment/de-envelopment model, an initial layer of nucleocapsid-associated tegument is acquired in the nucleus. A nuclear envelopment complex containing the conserved viral proteins, nuclear egress membrane protein (NEMP) and nuclear egress lamina protein (NELP), mediates a viral and cellular kinase-driven disassembly and rearrangement of the nuclear lamina that enables filled nucleocapsids to access the nuclear face of the inner nuclear membrane. In parallel, a subset of the population of viral glycoproteins is routed to the inner nuclear membrane, where they become part of the primary virion envelope as nascent virions bud into the lumen of the nuclear membrane. In comparison to mature infectious virions, primary enveloped virions present in the lumen of the nuclear membrane do not contain the full complement of virion glycoproteins and only a small subset of tegument proteins, but contain NEMP, which is not present in mature virions. Primary enveloped virions “infect” the cytoplasm from the lumen of the nuclear membrane by a membrane fusion process that for many herpesviruses is dependent on the same viral fusion proteins (gB and gH/gL) responsible for membrane fusion during initial infection at plasma or endocytic vesicle membranes. The envelopment/de-envelopment model is supported by ultrastructural, genetic, and biochemical data for members of all three *Herpesviridae* subfamilies. Nonetheless, as discussed further in Chapter 60, key elements of its proof are lacking, including identification of a fusion receptor on the luminal side of the outer nuclear membrane.

The third model is the simplest mechanistically. It is supported by limited ultrastructural and genetic data,⁶¹ and appears to apply in limited circumstances.

CYTOPLASMIC TEGUMENTATION, SECONDARY ENVELOPMENT, AND EGRESS

As delivered into the cytoplasm, nonenveloped nascent virions consist of nucleocapsids and a set of nucleocapsid-associated

tegument proteins (the inner tegument) that were acquired in the nucleus. The next assembly steps involve addition of the final complement of tegument proteins and some RNAs, and then acquisition of the mature envelope while budding into a cytoplasmic organelle from which the virion can be transported to the cell surface for release.^{48,57,84} Few mechanistic details are known of the tegumentation process. Virion membrane proteins must possess trafficking signals appropriate for being routed to exit organelles, where they form concentrated patches. Nucleocapsids are transported from the site of nuclear egress to their exit vesicle through associations with microtubule motors. Some tegument proteins interact with each other to form subassemblies that associate with the developing virion during transport to the exit organelle, and some tegument proteins associate with cytoplasmic projections of virion membrane proteins. When the necessary associations and structures have formed, tegumented nucleocapsids bud into the exit organelle, forming mature virions.

Herpesviruses can differ with respect to the organelle where they acquire their mature envelope. The unifying concept is that the exit organelle is adapted from an organelle that is normally involved in vesicular transport and delivery of cargo for release at the plasma membrane. Thus, HSV uses the trans-Golgi network, HCMV uses recycling endosomes, and HHV-6A uses multivesicular bodies. Vesicles containing enveloped virions are transported to the plasma membrane, where vesicle membranes fuse with the plasma membrane; mature virions are then released to the extracellular space where they can infect other cells in the same or different individuals.

Latency

Persistence in the host organism via cellular (or microbiologic) latency is a defining property of herpesviruses. Cellular latency is different from clinical (or organismal) latency, which is the period between infection and disease, and during which extensive lytic replication might be occurring at the cellular level (Figs. 59.3 and 59.7). In cells harboring latent virus, viral genomes generally take the form of closed circular molecules from which only a small subset of viral genes is expressed. Latent genomes retain the capacity to reactivate to a lytic state during which new infectious virions are produced. Latently infected cells differ from chronically or persistently infected cells in that infectious progeny are not produced during latency; the capacity to reactivate differentiates latent from abortive infections. Reactivation from cellular latency can result in disease due to a combination of the cellular and tissue damage directly caused by lytic virus replication, plus the immunologic responses to the reactivated lytic replication.

The precise molecular mechanisms that lead to establishment of and reactivation from the latent state are not fully understood and can differ from one herpesvirus to another. A common feature is epigenetic regulation of transcription during latency to ensure transcription of latency-specific transcription, as well as readily reversed suppression of lytic gene transcription.⁹⁴ Each herpesvirus establishes latency in a specific set of cells, with the cellular site of latency differing from one virus to another. For example, whereas HSV establishes latency in neurons of dorsal root ganglia, latent EBV is present primarily in B lymphocytes. Within an organism, a virus can be simultaneously latent in some cells and actively replicating in others. Thus, there are circumstances when virus is latent in essentially

all infected cells (as seems to be the case after clearance of primary VZV infection, and to a lesser extent, for HSV); virus is lytically active in a subset of infected cells, but there are no associated symptoms (perhaps the most common state for all of the human herpesviruses except for VZV); and lytic virus activity is of a nature that results in illness (with some cells remaining in a latent state) (Fig. 59.3).

Oncogenicity

Although many herpesviruses encode genes that can transform cells in experimental systems outside the context of viral infection, few herpesviruses are oncogenic (EBV and KSHV of the human herpesviruses). In only a few circumstances, such as the immortalization of B cells by EBV in the process of establishing its latent repository, is transformation or immortalization an integral part of the *in vivo* life cycle.⁸⁸ There is some irony in the development of recombinant herpesviruses for clinical application as oncolytic agents.¹⁵

HERPESVIRUS EVOLUTION

A number of reviews explore various aspects of herpesvirus evolution in depth.^{25,27,75,78}

Virus Origins

Although their precise origins remain open to speculation, the similarity of mechanisms and pathways of replication of herpesviruses with DNA phages cannot be explained totally on the basis of convergent evolution, and places the ancestry of herpesviruses at the early stages of the evolution of parasitism. Many genetic elements of herpesviruses trace to deep branches of evolutionary trees. Homologs of the terminase gene encoded by HSV-1 UL15 are found in all herpesviruses, including the fish and mollusk viruses²⁵; a related function is encoded by some DNA bacteriophages of the *Caudovirales*. Further evidence of a deep evolutionary relationship between herpesviruses and bacteriophages is the identification in their capsids of a shared unique fold that consists of three α -helices and two β -sheets.⁷

Numerous shared features suggest that herpesviruses trace to a common ancestor. The ancestral virus diverged into at least three highly diverged lineages, one represented by the alpha-, beta-, and gammaherpesvirus subfamilies that infect birds and mammals (the *Herpesviridae*), the others represented by the herpesviruses of oysters and of fish and amphibians (Fig. 59.2). Although there is little obvious genetic similarity between the latter herpesviruses and the herpesviruses of birds and mammals, their capsid structures are well conserved.^{9,31}

The ancestral herpesvirus of birds and mammals must have encoded homologs of most, if not all, of the core genes that are shared by the contemporary progeny. The three major lineages of these viruses emerged prior to the mammalian radiation.⁷³ According to one analysis, the alphaherpesviruses emerged prior to the beta- or gammaherpesviruses⁷³; a different method suggested that HHV-6 is closest to being a progenitor herpesvirus and that the alphaherpesviruses emerged relatively recently.⁵⁸ The evolutionary distances between closely related herpesviruses that infect different species—such as the rhadinoviruses KSHV (humans) and herpesvirus saimiri (squirrel monkeys)—suggest that in many instances viral speciation occurred at approximately the same time as did host speciation.^{73,89} The

situation is somewhat more complex in some closely related and more recently diverged lineages.⁷⁷ Thus, herpesviruses have an intimate shared evolutionary history with their hosts.

Gene Acquisition

Primordial Gene Acquisition

Although many eukaryotic genes have bacterial homologs, bacterial DNA polymerases are not related to eukaryotic replicative DNA polymerases. Rather, the eukaryotic DNA polymerases are related to a group of DNA polymerases encoded by some bacteriophages (e.g., T4); various archaea; and pox-, baculo-, and herpesviruses. This has led to the hypothesis that eukaryotic replication proteins had their origins in DNA viruses.¹²⁸

Other genes with primordial roots are also involved in the fundamental process of viral genome replication. Herpesvirus alkaline exonucleases have features in common with a superfamily of deoxyribonucleases that includes restriction endonucleases, exonucleases, and nicking enzymes, with members of the group being found in several virus families, including the phage lambda exonuclease.¹³ Herpesvirus primases (homologs of HSV-1 UL52) are members of the archaeoeukaryotic primase superfamily, a deeply rooted group whose origins trace to proteins of bacteriophages or bacteria.⁵⁵ Herpesviruses interact with many intracellular regulatory pathways, exemplified by the deubiquinating activity embedded in the conserved large tegument protein (homologs of HSV-1 UL36).¹¹²

In addition to connections to bacteriophages, homology has also been detected between the glycoproteins encoded by members of the HCMV RL11 gene family and human adenovirus E3 genes.²⁶

Evolutionarily Recent Gene Acquisition

Many of the more recently acquired genes are involved in modulation of host immune responses (reviewed in 27,96,106) and are of obvious host origin. Most of these genes are encoded in the viral genomes as single open reading frames that lack the intron/exon structure of their host homologs, indicating that their acquisition by the virus involved a reverse transcription step, possibly the product of a co-infecting retrovirus. An example of an immunomodulatory gene that was acquired independently in different herpesvirus lineages is the IL-10 homologs encoded by gammaherpesviruses, which branch with IL-10 homologs from primate species, and the IL-10 homolog of equine herpesvirus 2, which branches with the horse IL-10.⁵³ There are examples of recent introductions into limited lineages, such as a glycosyltransferase (core β -1,6-*N*-acetylglucosaminyltransferase-mucin) acquired from an ancestor of the African buffalo that is present only in viral lineages closely related to the gammaherpesvirus, bovine herpesvirus 4.⁶⁸ In addition to the primordial connections to DNA bacteriophages and other viruses, a more recent intervirus gene transfer is represented by the presence of homologs of the parvovirus *rep* gene in the genomes of some betaherpesviruses.^{122,129}

Mechanisms of Evolution

A number of rational mechanisms have been used to explain the development and divergence of herpesviruses; because of their time scale and net complexity, they are essentially impossible to prove directly. These mechanisms would have been used to assemble the current genomes from diverse sources such as those described previously, and include recombination-

based acquisition and subsequent evolution of chunks of cellular DNA, as well as transposition of viral or cellular DNA or RNA.^{12,119} Shifts in base and dinucleotide composition can occur as a function of viral DNA polymerase mutation rates or in response to concentrations of intracellular nucleotide precursors and pools. Intraspecies recombination enables relatively rapid exchange of information within a virus lineage. It requires simultaneous infection of the same cell by different viral genotypes, a recombination event, then selection and propagation of the recombinant. Despite the expected rarity of the simultaneous infection step, there is abundant evidence for intraspecies recombination occurring in nature,^{21,22,97,140} with recombination contributing to HSV-1 strain variability at a level comparable to mutation.¹⁰

The strategy of gene duplication and divergence has been used across the herpesvirus family, as exemplified by the evolution of the dUTPase gene of the mammalian/avian/reptilian herpesviruses, which appears to have undergone a duplication and subsequent fusion that involved permuting the order of its subdomain.^{29,72} Further duplication and divergence events led to the current family of genes that encode proteins with dUTPase function, as well as proteins that lack residues that are essential for dUTPase activity, and have diverse or unidentified functions. Some of these proteins are essential for viral replication, whereas others are not. The betaherpesviruses have exploited this duplication and divergence strategy extensively, with HCMV encoding five gene additional families that each have from 2 to 12 members.¹⁸ Modifying a protein that is already able to be incorporated into the virion to execute a new function is a much smaller evolutionary challenge than a *de novo* strategy that requires simultaneous or successive development of function and its incorporation into virions. Thus, the strategy of adapting functionally flexible structural scaffolds to new purposes can confer a significant selective advantage.

Functional Convergence

An important regulatory circuit for T-cell activation operates through a member of that tumor necrosis factor receptor superfamily, the herpesvirus entry mediator (HVEM). This pathway is modulated by HSV-1 by binding of gD to HVEM, which blocks the binding of two regulatory ligands of HVEM, LIGHT, and BTLA. HCMV UL144 encodes a protein that mimics the BTLA binding site on HVEM, blocking the BTLA–HVEM interaction.¹⁹ Thus, these divergent herpesviruses have evolved independent mechanisms for modulating this immune regulator. There are numerous parallel examples, including the previously mentioned intersections with paths that regulate interferon and apoptosis.

Herpesvirus Phylogeny

The virus lineage that resulted in the present day alpha-, beta-, and gammaherpesvirus subfamilies is rooted at approximately 400 Ma (million years before the present).⁷⁶ As mentioned, to a first approximation, relationships among virus species within the major subdivisions of the alpha-, beta-, and gammaherpesvirus subfamilies mirror host phylogeny.

In contrast to the beta- and gammaherpesviruses, the alphaherpesvirus lineage includes viruses of reptiles and birds. Analysis of limited sequence data from several reptilian herpesviruses suggests that the avian and mammalian alphaherpesviruses descended from a lineage that included the reptilian

viruses. Current information cannot discriminate between the possibilities that the reptilian and mammalian viruses co-evolved with their hosts, and the avian lineages arose via transfer from reptiles or mammals; or the reptilian and avian viruses co-evolved with their hosts, with the mammalian viruses arising via a transfer event.⁷⁶ It remains to be determined whether there are single or multiple nodes through which the reptilian viruses connect to the alphaherpesvirus lineage.^{76,132}

Phylogenetic analyses can lead to testable hypotheses. Fleshing out of the rhadinovirus phylogenetic tree by amplifying novel viruses from a host of nonhuman primates has led to identification of two sublineages of Old World rhadinoviruses, each of which has identified homologs in chimpanzees and gorillas or gibbons. KSHV belongs to one of these lineages, but a human virus has not been identified for the other, leading to an ongoing directed search for a potential novel human gammaherpesvirus.^{35,113}

Host Interactions and Herpesvirus Evolution

Some viruses have evolved to rapidly spread new genotypes through the host population, such as can occur via the rapid global distribution by birds of newly reassorted influenza viruses. This is in marked contrast to viruses such as KSHV that have been relatively stable in their hosts over a time course that corresponds to the global radiation of humans from our African origins.⁴⁹ Other herpesviruses also show marked geographically defined genotype distributions.

A concept of some relevance is that of the “genetic budget” of viruses and its effect on virus–host interactions.^{17a} According to this theory, the error-prone replication of the generally smaller RNA viruses is a more primitive/crude escape mechanism that works over the short term and can be associated with significant host damage. With the greater genetic budget afforded by their larger genomes, viruses such as herpesviruses have acquired an array of genes and genetic functions that allow a more finely regulated virus–host interaction that functions over the course of a long-term relationship between the virus and an infected individual.

In summary, herpesviruses are well adapted to their hosts. In the natural immunocompetent host, fatal infections are rare; from the point of view of viral survival, fatal infections are counterproductive because they do not lead to transmission of virus. This is not always the case when herpesviruses infect a heterologous host, such as the frequently fatal outcomes of infection of cattle with pseudorabies virus, of humans with simian B virus, and the severe malignant catarrhal fever in cattle and bison that is caused by infection with *Ovine herpesvirus 2*, a virus that is a relatively benign inhabitant of sheep.³⁴ Thus, in addition to adaptation to specific cellular niches, many of the dispensable genes must also function to strike the optimal balance between virus growth in the host and a combination of avoidance and stimulation of host responses so that the virus can persist in populations of organisms over an evolutionary time scale.

But of all such cases, the most formidable were those which took place about the pubes and genital organs. Such was the nature of these cases when attended with sores, and proceeding from an external cause; but the same things occurred in fevers, before fevers, and after fevers.

Hippocrates, "Of the Epidemics," 400 BCE

INTRODUCTION AND HISTORY

The publication of the sixth edition of this book approaches the 100th anniversary of the formal recognition of herpes simplex virus (HSV) as an infectious agent,⁹⁶¹ having met the requirements of Koch's postulates. A revisionist historian would point to the facts that the lesions caused by HSV may have been described in the ancient literature millennia ago, and that the infectious nature of the disease was well described more than two centuries ago, as was the experimental transmission of the virus from person to person. Thus, descriptions of genital lesions that resemble those caused by HSV were described in a Sumerian tablet from the third millennium BC and in the Ebers Papyrus (c. 1500 BC). Hippocrates used the Greek word *herpes* to describe lesions that seem to creep or crawl along the skin. In all instances, the lesions described in these early accounts could have been attributed to viral, fungal, or parasitic infections virtually unknown today, to concurrent infections with several pathogens, or even to cutaneous malignancies. Celsus may have been the first to describe an actual herpetic lesion as initially round but then diffused as a serpent to form a belt—a description that would fit varicella-zoster virus better than HSV. Galen elaborated on Herodotus' description and indicated that the lesions recurred at the same anatomic site. In the intervening centuries between Galen's initial description of lesions similar to those caused by HSV and the 17th century, the term *herpes* was applied to many different skin ailments.⁹⁶¹ Probably the most relevant to our age are the writings of John Astruc, physician to King Louis XIV.

At that time, French prostitutes (*puellae publicae*) were under medical surveillance, Astruc and others studied their afflictions, and he was the first to describe *herpes genitalis*.³⁹ A most enlightening description of recurrences of genital lesions was published by Unna in 1883.¹¹⁷² He wrote that herpes was "*so to say a vocational disease*," recognized as being "*one of the most benign of affections both to the patient and her public*." Shortly afterward, the first book dedicated to herpes—*Les Herpes Genitiaux*—was published.²⁷⁶ In 1896, Fournier wrote about the diagnosis and treatment of genital herpes.³⁴³ His advice was "*For recurrent herpes the general treatment of arthritis* [by which he may have meant inflammation and pain] *may be necessary. As far as hygiene, forbid alcohol, tobacco, also wine fatigue, and sexual excesses*".³⁴³ But it was Vidal¹¹⁹⁰ who had the dubious distinction of passing infection from one human to another and thus proving beyond a doubt that HSV was infectious. While these human studies were being performed, Gruter initiated a series of animal studies that unequivocally demonstrated the infectious nature of HSV.³⁹⁸ He showed how HSV could be transmitted serially from rabbit to rabbit, and although Gruter published his data years after they were completed and after Lowenstein,⁶⁸³ it is to him that the virology community gives credit for the isolation of HSV.

Although HSV was recognized as an infectious agent in the last quarter of the 19th century, many more years passed before the connection between HSV and recurrent infections was finally established. In the 1930s, one of the milestones of HSV biology was the observation made by Andrews and Carmichael that recurrent infections occurred only in adults who carried neutralizing antibodies, an occurrence in sharp contrast to the behavior of other known infectious agents at that time. Their article stimulated an international debate that ultimately shaped the perception of HSV as a disease agent. On one extreme, Doerr, a doyen of European virology of the time, stated that HSV infections in humans resulted from the endogenous production of a virus-like agent by the cell, under the influence of certain stimuli, and were not caused by exogenous infection.²⁸⁴ Once the agent had been produced, it would act on the cells of susceptible animals (not man) as a true virus. One year later, Burnet and Williams articulated the modern view that "*Herpes simplex infections, however, once contracted, seem to persist for life. The virus remains for the most part latent; but under the stimulus of trauma, fever, as so forth it may at any time be called into activity and provoke a visible herpetic lesion*".¹⁴¹ In retrospect, however, Doerr had come perilously close to understanding the true nature of latency, namely that endogenous virus production by the cell is based on information supplied by the viral DNA retained within the cell. The modern age of HSV research had arrived.

HSVs were the first of the human herpesviruses to be discovered and are among the most intensively investigated of all viruses. Their attractions are their biological properties, particularly their abilities to cause various infections, to remain latent in their host for life, and to reactivate to cause lesions at or near the site of initial infection. They serve as models and tools for the study of translocation of proteins, synaptic connections in the nervous system, membrane structure, gene regulation, gene therapy, cancer therapy, and myriad other biological problems, both general to viruses and specific to HSV. For years, their size and complexity served as formidable obstacles to intensive research. More than 40 years passed from the time

of their isolation until Schneeweis¹⁰¹⁶ demonstrated that there were in fact two serotypes of HSV—HSV-1 and HSV-2—whose formal designations under the International Committee on Taxonomy of Viruses (ICTV) rules are now the two species human herpesviruses 1 and 2.⁹⁵¹ Not until 1961 were practical plaque assays published,⁹⁵⁷ and only much later were the genome sizes and the extent of homology between these two viruses reported. This chapter recounts well-established facts; however, its main emphasis is on burning issues—the problems whose time has come.

To the prefaces of earlier editions, which we affirm but are not repeated here, we add two additional comments. Foremost, the field has grown enormously since the dawn of the molecular biology of HSV more than 45 years ago. Studies on HSV are entering, at last, a most exciting period for two reasons. First, the words *structure and function* are beginning to have an operational meaning. Second, HSV gene products have become powerful probes for the study of cellular metabolic pathways. Host factors crucial to virus multiplication and, potentially, to latency are being identified. The armamentarium for a major assault on the mysteries underlying the biology of these viruses is in place and reflects the contributions of many laboratories over many, many years. However, we are also confronted with the fact that only a fraction of viral gene products are extensively studied and that for many products their reason for existence has not been established.

The literature has grown *pari passu* with the field and tasks our capacity to place myriad collected data into a comprehensible total. The task before us was far greater for not having followed Ludwig Wittgenstein's dictum that "*Whereof one cannot speak, thereof one must be silent,*" but chapters of citations bereft of commentary are dull. The decision to avoid assembling an annotated bibliography was in large part dictated by the space available to us. As a result of these space limitations, the references from 2008 to the present are listed in the book, whereas all of the cited references can be found in the eBook form of this publication.

VIRION STRUCTURE

The HSV virion consists of four elements: (a) an electron-opaque core containing the viral DNA, (b) an icosahedral capsid surrounding the core, (c) a largely unstructured proteinaceous layer called the *tegument* that surrounds the capsid, and (d) an outer lipid bilayer envelope exhibiting spikes on its surface⁹⁵² (Fig. 60.1A). Early studies defined the structure of the HSV virion through electron microscopy and biochemical analysis of the virion components. More recent electron cryo-microscopy studies have defined the nucleocapsid structure to 8.5 Å resolution.¹³¹⁹ The most detailed analysis of the whole virion used cryo-electron tomography to define its structure to 7-nm resolution³⁹⁷ (see Fig. 60.1B,C). This study defined the virion as a spherical particle with an average diameter of 186 nm, which extended to 225 nm with spikes included. The nucleocapsid was located in an eccentric position with one edge of the nucleocapsid close to the envelope and the other, the distal pole, 30 to 35 nm from the envelope. The tegument showed a particulate structure with some 7-nm filaments apposed to the membrane. The tegument cap on the distal pole was connected to the envelope by 4 nm wide "linkers."

FIGURE 60.1. Structure of the herpes simplex virus (HSV) virion.

A: Electron micrograph of a negative-stained HSV-1 virion. The envelope, tegument, capsid, and core are indicated. (Micrograph provided by Travis Taylor.) **B:** Surface image of HSV derived from cryo-electron tomography.³⁹⁷ Glycoprotein spikes are shown in *yellow*, and the membrane is *blue*. **C:** Cutaway view of the virion interior derived from cryo-electron tomography. Capsid is shown in *light blue*, the tegument cap is shown in *orange*, the envelope is *dark blue*, and the glycoprotein spikes are *yellow*. (Parts B and C courtesy of Alasdair C. Steven.)

Virion Proteins

Early studies on purified HSV-1 virions suggested that they contain more than 30 distinct proteins that were designated as virion polypeptides (VP) and given serial numbers.^{437,1079} HSV proteins have also been named based on serial numbering of the virion proteins on a gel (e.g., VP1/2), on the open reading frame (ORF) encoding them (e.g., U₁8), or as infected cell proteins (ICPs; e.g., ICP5). Mass spectrometry analysis of purified extracellular virions demonstrated several host proteins,⁶⁸² although the critical issue will be to determine if any host proteins are essential for virion structure. Of the approximately 30 known and 10 suspected virion proteins, at least 11 are on the surface of the virion (accessible to antibody) and at least 10 are glycosylated.

Core

The core contains the double-strand (ds) DNA genome wrapped as a toroid³⁵⁶ or spool¹³¹⁸ in a liquid crystalline state.¹¹¹ A small fraction of the virion DNA may be circular.^{878,1103} The viral DNA genome is described in detail later.

The core does not contain highly basic proteins, including histones, that would neutralize the negative charges on viral DNA to allow proper folding within the capsid; however, highly purified virions do contain the polyamines spermidine and spermine in a nearly constant ratio of $1.6 \pm 0.2:1$, or approximately 70,000 molecules of spermidine and 40,000 molecules of spermine per virion.^{374,376} The polyamines appear

to be tightly bound and cannot be exchanged with exogenously added, labeled polyamines. Disruption of the envelope with nonionic detergents and urea removed the spermidine but not the spermine. The spermine contained in the virion is sufficient to neutralize approximately 40% of the DNA phosphate.³⁷⁶

Tegument

The space between the undersurface of the envelope and the surface of the capsid, designated as the tegument,⁹⁵² is largely unstructured, except for the fibrils described previously and some apparent icosahedral structure around the pentons¹³¹⁸ and is comprised of at least 18 viral proteins (see the following gene list). The most notable of the proteins associated with the tegument are the VP16 virion transactivator protein (also known as α -trans-inducing factor or α TIF, encoded by the *U_L48* ORF); the virion host shutoff (VHS) protein (*U_L41*) VP22 (*U_L49*), which was reported to have the ability to spread cell to cell³¹²; and a very large protein (VP1-2; *U_L36*), which plays a role in DNA release at the nuclear pore during viral entry.⁷³ Other tegument proteins include *U_L14*, *U_L17*, VP11/12 (*U_L46* gene), VP13/14 (*U_L47*), *U_S9*, *U_S10*, and *U_S11*. Recent studies are starting to define the protein–protein interactions both within the tegument and between the tegument and capsid and envelope proteins.¹¹⁹³

Highly purified HSV virions contain cellular and selected viral gene transcripts.¹⁰²¹ These are likely packaged in the tegument because three RNA binding proteins (*U_S11*, *U_L47*, and *U_L49*) were identified in the tegument.¹⁰²³

Capsid

The capsid is comprised of 162 capsomers, including 140 hexons, 11 pentons, and one portal, arranged in a T = 16 icosahedral symmetry. Cryo-electron microscopy studies have shown that the HSV nucleocapsid is composed of an outer layer arranged in a T = 16 symmetry and an intermediate layer organized in a T = 4 lattice.¹⁰¹⁸ The same study concluded that the outer and intermediate layers are organized so that channels along their icosahedral twofold axes coincide, forming a direct pathway and potential channel between the DNA layer and the exterior of the virion.¹⁰¹⁸ Another study of intact virions has shown that the channel is plugged, possibly with tegument proteins.¹³¹⁸

The outer shell of the capsid is composed of four viral proteins, VP5 (*U_L19*), VP26 (*U_L35*), VP23 (*U_L18*), and VP19C (*U_L38*). VP5, the major capsid protein, is present in five copies in each penton capsomere and six copies in each hexon capsomere in this icosahedral shell. VP26 is present in six copies as a ring on top of the VP5 subunits on each hexon.¹³²⁰ Triplexes made up of one VP19C molecule and two VP23 molecules link adjacent capsomeres as a result of the triplex forming a pseudotrimer with each subunit interacting in a roughly similar manner with two capsomeres.¹³¹⁹ The capsid also contains the *U_L6* protein, which forms a dodecamer thought to form a portal through which viral DNA is packaged¹¹⁶³ and VP24 (*U_L26*), the protease that processes the scaffolding during DNA encapsidation. The *U_L16* protein may be a capsid-associated protein because it plays a role in DNA encapsidation.

Envelope

The envelope consists of a lipid bilayer with as many as 13 distinct viral glycoproteins embedded in it. The virion enve-

lope glycoproteins are gB (VP7 and VP8.5, encoded by the *U_L27* gene), gC (VP8, *U_L44*), gD (VP17 and VP18, *U_S6*), gE (VP12.3 and VP12.6, *U_S8*), gG (*U_S4*), gH (*U_L22*), gI (*U_S7*), gK (*U_L53*), gL (*U_L1*), and gM (*U_L11*). The presence of gJ (*U_S5*) and gN (*U_L49.5*) in virions has not been demonstrated. Virion envelopes also contain at least two (*U_L20* and *U_S9*) and possibly more (*U_L24*, *U_L43*, and *U_L34*) nonglycosylated intrinsic membrane proteins.

Lipids

It has been assumed that HSV acquires the envelope lipids from its host. The hypothesis that the lipid composition of the viral envelope is determined by the host was supported by the observation that the buoyant density of the virus was host cell dependent on serial passage of HSV-1 alternately in HEp-2 and chick embryo cells.¹⁰⁷⁸ More recent studies¹¹⁷⁹ suggest that the virion lipids are similar to those of cytoplasmic membranes and different from those of nuclear membranes of uninfected cells.

STRUCTURE AND SEQUENCE ARRANGEMENT OF VIRAL DNA

The bulk of packaged HSV DNA is linear and double stranded.⁵⁴⁶ The ends of the genome are probably held together or are in close proximity inasmuch as a small fraction of the packaged DNA appears to be circular and the bulk of the linear DNA circularizes rapidly in the absence of protein synthesis after it enters the nuclei of infected cells.⁸⁷⁸ DNA extracted from virions contains ribonucleotides, nicks, and gaps.^{94,351} Based on physical characterization studies, the HSV genome was originally estimated to be approximately 150 kilo base pair (kbp), with a G + C content of 68% for HSV-1 and 69% for HSV-2.⁵⁴⁶ Complete sequencing of the HSV-1 strain 17 genome described the genome as 152,260 bp and 68.3% G + C (GenBank sequence accession number NC_001806),⁷²⁷ and minor updates altered this sequence to 152,261 bp.²⁸⁵ Complete sequencing of the HSV-2 strain HG52 genome defined it as 154,746 bp and 70.4% G + C (GenBank sequence accession number NC_001798).²⁸⁵ However, these numbers include only single copies of the *a* sequence at the ends of the L component and do not take into account the variation in the size of the *a* sequences (200–500 bp each) or the variable number of direct repeats present throughout the genome but especially in the inverted repeats flanking the L and S components.

Illumina high throughput sequencing further defined the genomic sequence of two HSV-1 viruses: the F laboratory strain and the H129 clinical isolate.¹¹¹⁴ This analysis defined the unique and single copies of the repeated sequences of the genomes and based the numbers of repeats on the strain 17 prototype genome. Comparison of the three sequences showed a limited amount of sequence diversity, less than 0.7%, between any pair of the viruses.¹¹¹⁴

The HSV genome can be viewed as consisting of two covalently linked components, designated as L (long) and S (short) (Fig. 60.2). Each component consists of unique sequences bracketed by inverted repeats.¹¹⁹⁸ The repeats of the L component are designated *ab* and *b'a'*, whereas those of the S component are *a'c'* and *ca* (see Fig. 60.2). The number of *a* sequence repeats

FIGURE 60.2. Schematic representation of the arrangement of DNA sequences in the herpes simplex virus (HSV) genome. **A:** The domains of the L and S components are denoted by the arrows. The second line shows the unique sequences (thin lines) flanked by the inverted repeats (boxes). The letters above the second line designate the terminal a sequence of the L component (a_L), a variable (n) number of additional a sequences, the b sequence, the unique sequence of the L component (U_L), the repetitions of the b sequence and of a variable (m) number of sequences (a_m), the inverted c sequence, the unique sequence of the S component (U_S), and finally the terminal a sequence (a_S) of the S component. **B:** The HindIII restriction endonuclease map of HSV-1 (F) strain for the P, I_S , I_L , and I_{S+L} isomers of the DNA. Note that because HindIII does not cleave within the inverted repeat sequences, there are four terminal fragments and four fragments spanning the internal inverted repeats in concentrations of 0.5 and 0.25 M, respectively, relative to the concentration of the viral DNA.

at the L–S junction and at the L terminus is variable; thus, the HSV genome can then be represented as

$$a_L a_n b - U_L - b' a'_m c' - U_S - ca_S,$$

where a_L and a_S are terminal sequences with unique properties described below, and a_n and a_m are terminal a sequences directly repeated 0 or more times (n) or present in one to many copies (m).^{666,948,949,1198,1202} The overall structure of the a sequence is highly conserved; however, it consists of a variable number of repeat elements. In the HSV-1 F strain, the structure of the a sequence can be represented as

$$DR1 - U_b - DR2_n - DR4_m - U_c - DR1,$$

with DR1 being a 20-bp direct repeat, U_b being a 65-bp unique sequence, DR2 being a 12-bp direct repeat present in 19 to 23 copies per a sequence, DR4 being a 37-bp direct repeat present in 2 to 3 copies, U_c being a 58-bp unique sequence, and a final copy of DR1.^{759,760} Adjacent a sequences share an intervening DR1. The size of the a sequence varies from strain to strain, reflecting in part the number of copies of DR2 and DR4. Linear virion DNA contains asymmetric terminal a sequence ends. The terminal a sequence of the L component (a_L) contains a truncated DR1 with 18 bp and one 3' nucleotide extension, whereas the terminal a sequence of the S component (a_S) ends with a DR1 containing only 1 bp and one 3' overhanging nucleotide.⁷⁶¹ The two truncated DR1 sequences form a complete DR1 upon circularization.

The L and S components of HSV are found inverted relative to one another, to yield four linear isomers (see Fig.

60.2B). Populations of unit-length DNA from wild-type virus-infected cells consist of equimolar concentrations of the four predicted isomers.^{263,430} The isomers have been designated as P (prototype), I_L (inversion of the L component), I_S (inversion of the S component), and I_{S+L} (inversion of both S and L components).⁴³⁰ The first evidence for the existence of repetition of terminal sequences in an inverted orientation was from electron microscopic studies of denatured HSV-1 DNA allowed to self-anneal¹⁰³¹ and partial denaturation profiles of HSV DNA, which revealed that the terminal repeats are also repeated internally and that the repeats flanking the L component differ from those of the S component in size and sequence arrangement.¹¹⁹⁸ The demonstration that restriction endonucleases that cleave outside the inverted repeats yield four terminal fragments, each present in one-half of the molecules (also called *half molar* or *0.5-M fragments*), and four L–S component junction fragments that are each present in one-fourth of the molecules (also called *quarter molar* or *0.25M fragments*)⁴³⁰ (see Fig. 60.2B), as well as analyses of the partial denaturation profiles of Wadsworth et al,¹¹⁹⁸ supported the conclusion that the L and S components can invert relative to each other.

The internal inverted repeat sequences are not essential for growth of the virus in cell culture; thus, mutants from which portions of unique sequences and most of the internal inverted repeats have been deleted have been obtained in all four arrangements of HSV DNA.^{498,879} The genomes of these mutants do not invert and are frozen in one arrangement of the L and S components, although all retain their viability in cell culture.

Herpes Simplex Virus Genetic Variation

Herpes Simplex Virus 1 Versus Herpes

Simplex Virus 2 Variation

Comparison of the complete DNA sequences of an HSV-1 and HSV-2 genome confirmed the colinearity of the two genetic maps and showed an overall identity of 83%.²⁸⁵ Nevertheless the two genomes differ with respect to the location of endonuclease cleavage sites in their genomic DNAs and in the apparent sizes of the encoded proteins. The variations with respect to restriction endonuclease cleavage sites and apparent size of the proteins were used to map the approximate genomic location of genes on the basis of analyses of HSV-1 X HSV-2 recombinants.^{716,768,896}

Herpes Simplex Virus 1 Strain Variation

The first evidence of HSV-1 strain polymorphisms emerged from studies of virion structural proteins and indicated that nonglycosylated proteins vary sufficiently in electrophoretic mobility to be used as strain markers.⁸⁶⁴ Although specimens from epidemiologically related individuals appeared to yield similar electrophoretic profiles, the usefulness of virion proteins as markers for molecular epidemiologic studies was limited by the effort required to purify virions for such analyses.

At the DNA level, differences between HSV-1 strains appear to result from (a) base substitutions that may add or eliminate a restriction endonuclease cleavage site, and on occasion, change an amino acid and (b) variability in the number of repeated sequences present in a number of regions of the genome (e.g., $\gamma_134.5$, U_511 , etc.).^{195,941} The restriction endonuclease cleavage patterns of a given strain are relatively stable, whereas the numbers of repeats are not.^{135,429,950,1151} Thus, no changes in restriction endonuclease patterns were noted in isolates from the same individual over an interval of 13 years or in genomes of an HSV-1 strain passaged serially numerous times in cell culture. However, restriction endonuclease site polymorphisms were readily noted in isolates from epidemiologically unrelated individuals.^{416,960} On the basis of these properties, restriction endonuclease site polymorphism was used in several epidemiologic studies of HSV transmission in the human population.^{135,950,960} In addition, restriction endonuclease analysis of virus isolates has been used to trace the spread of infection from patients to hospital personnel,¹³³ from patient to patient,⁶⁵³ and from hospital personnel to patient.^{4,134} One paper⁹⁸² reported clustering of divergent sites along geographically and racially distinct areas. Although these authors concluded that the evolution of HSV-1 may be host dependent, it seems more likely that random mutations were conserved and dispersed in different populations.

The limited amount of phylogenetic analysis of HSV genomes conducted thus far has revealed limited sequence diversity among HSV isolates. Sequence comparison and phylogenetic analysis of the U_54 , U_57 , and U_58 genes of 28 HSV-1 clinical isolates showed at most 2% divergence between isolates but revealed three major clades.⁸¹⁵ Sequence analysis of the U_54 , U_57 , and U_58 genes of 27 HSV-2 clinical isolates from Tanzania, Norway, and Sweden showed only 0.4% divergence; nevertheless, at least two genotypes were identified.⁸¹⁶ Thus far, no HSV-2 low-passage clinical isolate genomes have been sequenced, and it will be interesting to determine how these differ in DNA sequence from the highly attenuated HSV-2 strain HG-52 viral genome. Sequence analysis of HSV genomes has

shown that HSV-1 and HSV-2 diverged 8 million years ago²⁸⁵ and the HSV-1 clades diverged about 700,000 years ago.⁸¹⁷ There is evidence of high-level recombination in the evolution of HSV genomes^{119,815,816,817}; therefore, this could help to explain the limited amount of genetic diversity found in current HSV clinical isolates.

Viral Genes: Pattern of Organization and Expression

Distribution and Organization of Transcriptional Units

HSV DNA encodes, by current count, at least 90 unique transcriptional units. (The HSV-1 and HSV-2 genomic sequences and gene maps can be found at the following websites: <http://stdgen.northwestern.edu> and <http://www.viprbrc.org>.) At least 84 of these transcriptional units encode proteins. As described in more detail later, these genes are classified into at least three general kinetic classes: α or immediate-early, β or early, and γ or late genes. The key elements of genome organization are as follows:

1. With three known exceptions, each viral transcript encodes a single protein. In the first exception, a single transcript serves as the template for both ORF P and ORF O proteins. Protein synthesis is initiated from a single methionine but diverges between the 1st and 35th codons to yield different polypeptides.⁹¹⁶ Second, the U_L26 gene encodes a polypeptide that cleaves itself to form two proteins. The N-terminal product functions as a protease. The C-terminal product, ICP35a,b, is a component of the capsid scaffolding. The third exception is the messenger RNA (mRNA) that encodes the U_L3 protein. This RNA, 2.9 kb in size, contains the ORFs of U_L1 , U_L2 , and U_L3 ; however, U_L1 and U_L2 proteins are encoded by distinct mRNAs.¹⁰⁵² The mechanism of expression of the U_L3 protein is unknown.
2. Many clusters of transcriptional units are 3' co-terminal. In addition, these clusters may be arranged either head to head, head to tail or tail to tail. The precise transcriptional initiation sites are not known for all transcriptional units. In many instances, but especially late in infection, transcriptional termination sites are ignored with the consequence that run-on transcripts of giant size are present along with the properly terminated transcripts.
3. There are several instances of transcriptional units wholly embedded in the coding sequence contained in the larger transcript. In each instance, the transcripts are 3' co-terminal, and the coding sequences of the smaller mRNA are identical to a C-terminal portion of the protein encoded by the larger mRNA. For example, the transcript encoding $U_51.5$ is 3' co-terminal with that of the $\alpha 22$ gene. The protein encoded by $U_51.5$ contains the 250 C-terminal residues of the 420-residue product of the $\alpha 22$ gene.¹⁶⁰ A similar relationship exists between U_L26 and $U_L26.5$ ^{657,658} and between U_53 and $U_53.5$.⁸⁸⁶ The two products may differ in function. For example, both U_53 and $U_53.5$ are protein kinases that phosphorylate similar substrates. However, whereas U_53 protects cells from proapoptotic viral or cellular proteins, $U_53.5$ protein kinase does not.⁸⁸⁶
4. Some of the expressed ORFs are antisense to each other. These include $\gamma_134.5$ and ORF P; U_L43 and $U_L43.5$, and gB and $U_L27.5$. The existence of additional antisense ORFs cannot be excluded.

5. Few of the transcripts accumulating in infected cells arise as a consequence of splicing of RNA. In only a few cases ($\alpha 0$ and U_L15 of HSV-1 and both genes plus $\gamma_134.5$ of HSV-2) are there introns within coding domains. The intron of U_L15 is transcribed antisense to U_L15 and encodes two ORFs, U_L16 and U_L17 .⁷²⁷ In all other cases (genes encoding ICP22, ICP47), the introns are in the 5' noncoding domains. The major intron of ICP0 is more stable than the mRNA encoding the protein and is translocated into the cytoplasm. The differences between viruses carrying wild-type and intronless $\alpha 0$ genes add urgency to the investigation of the role of this intron on the course of viral infection.
6. Several transcripts appear to not encode proteins. Those best known are the latency-associated transcripts (LATs), described in the Latent Infection section and the *Ori_s* mRNA that is expressed late in infection and is 3' co-terminal with the mRNA encoding ICP4. The functions of these RNAs in productive infection are not known.

Functional Organization of Herpes Simplex Virus Genomes

α Genes Map Near the Termini of the L and S Components

$\alpha 0$ and $\alpha 4$ map within the inverted repeats of the L and S components, respectively, and are therefore each present in two copies per wild-type genome. However, a single copy of each is sufficient inasmuch as mutants lacking the internal inverted repeats are viable but are attenuated for growth in animals.⁸⁷⁹ With few exceptions, β and γ genes are scattered in the unique sequences of both the L and S components. The exceptions are the $\gamma_134.5$ and *ORF P* genes located in the reiterated sequences flanking the L component between the terminal *a* sequence and the $\alpha 0$ gene. At present, only two functional gene clusters are strikingly apparent, although their significance is uncertain: The β genes specifying the DNA polymerase and the ICP8 single-stranded DNA binding protein flank the L component origin of DNA synthesis (*Ori_L*), and the γ genes specifying membrane glycoproteins D, E, G, I, and J map next to each other within the unique sequences of the S component.

Genetic Techniques for the Identification of Gene Product Function

The various genetic techniques used for analysis of HSV have been described in depth previously⁹⁵⁶; therefore, we will review this area only briefly. Key to the identification of viral functions and mapping of viral genes encoding these functions are conditional lethal, such as temperature-sensitive (ts) and null mutants. Earlier studies of ts mutants identified approximately 30 complementation groups,¹²³⁰ which was enormously helpful in identifying and mapping some genes and the functions of their gene products. Nevertheless, ts mutant phenotypes placed constraints on the range and types of mutants that could be isolated. Thus, several methods have been developed for localized mutagenesis of the viral genome. Genetic alterations have been introduced into the viral genome by a co-transfection procedure involving the introduction of infectious viral DNA with a viral DNA fragment that contains a marker or mutation to be introduced into the viral genome by a double cross-over event.^{561,976,1102} This has been used for marker rescue mapping of viral ts mutants, introduction of markers into a viral genome

(marker transfer,^{561,976} and for introduction of mutations into a viral genome.^{199,221} Alternatively, the second major technique is based on the use of bacterial artificial chromosomes to propagate the viral genome in bacterial cells. Mutations can be introduced into the HSV sequences, and introduction of the recombinant bacterial artificial chromosome into mammalian cells yields infectious virus.⁴⁶⁷ The genomes cloned as bacterial accessory chromosomes are also amenable to random insertional mutagenesis by transposons.

A protocol for site-specific insertion/deletion of viral genes was based on selection of recombinants generated by double recombination through homologous flanking sequences between an intact viral DNA molecule and a DNA fragment containing an insertion or deletion and a selectable marker.⁸⁹³ The selectable marker used in these studies was the viral thymidine kinase (*tk*) gene because (a) it can be deleted from the HSV genome without affecting the growth of virus in cell culture; (b) a plasmid-borne *tk* gene can be altered so that it cannot recombine by double cross-over to repair the deletion in the genomic *tk* gene; (c) viruses carrying a functional *tk* gene can be selected against by plating viral progeny in the presence of nucleoside analogs phosphorylated by the viral thymidine kinase (TK) e.g., Ara T; and (d) viruses expressing the *tk* gene can be selected for by plating the virus in TK⁻ cells in medium containing methotrexate or aminopterin, which blocks the conversion of thymidine monophosphate (TMP) from 2'-deoxyuridine 5'-monophosphate (dUMP) by thymidylate synthetase and precludes the *de novo* pathway of TMP synthesis. This procedure permits the selection of viable mutants with deletions or insertions in genes that appear to be nonessential for growth in cells in culture.

A second popular approach for mutagenesis of a specific gene is to replace the gene with an expression cassette containing *Escherichia coli lacZ* coding sequences so that the β -galactosidase enzyme is expressed by the recombinant virus. The recombinant virus can be identified by the formation of blue plaques in the presence of chromogenic substrates such as X-GAL.³⁸⁴ If the recombinant virus can be isolated and propagated on normal cells, such as Vero cells, the mutated gene is considered to be nonessential. Insertion of a green fluorescent protein (GFP) expression cassette into a gene results in a virus that gives a green fluorescent plaque,⁹⁸⁹ and recombination of other sequences into the genome to replace the GFP cassette to give a virus that forms a nonfluorescent plaque also provides a screen for introduction of new sequences into a viral genome.¹²²²

If the viral gene is essential for growth in that cell line, stable complementing cell lines have often been used to propagate these null mutant viruses.²⁶⁵ In this protocol, the gene to be mutated is transfected into and stably maintained in a cell line that serves as the complementing cell line. The complementing cell line is then transfected with intact viral DNA and the mutated DNA fragment. The progeny viruses are screened for mutants that form blue plaques or multiply only in the complementing cells.²⁶⁵ It should be emphasized that the procedures for generating site-specific mutations can introduce unintended mutations at distant sites. The obvious and necessary control is to restore the original sequence and then compare parent, mutant, and rescued virus for the predicted phenotype of the mutation.

The genes known to be dispensable for viral replication in cells in culture are listed in the Gene Functions List. It should be

stressed that most of the dispensable genes are required for replication in experimental animal systems and that in no instance has a virus lacking a dispensable gene been isolated from human lesions (although viruses that fail to react with a specific monoclonal antibody are readily isolated).

Genes dispensable for viral replication in cells in culture fall into several groups whose products are involved in entry of HSV into cells, regulation of gene expression, posttranslational modification of proteins, exocytosis, inhibition of host response to infection, and spread of virus from cell to cell. It could be predicted that viral genes that specify products whose functions are identical and interchangeable with those of cellular genes would be dispensable, at least in cells that express these functions. In this category are the *tk* gene and the genes specifying ribonucleotide reductase. The observation that some virion proteins are dispensable for infection and replication of virus at least in cell culture was very puzzling for many years. Although we cannot exclude the possibility that cells express proteins with similar functions that complement the deletion mutants, a more likely scenario is that cells in culture express many more genes than cells *in situ* in animal organs. Moreover, recent studies have demonstrated that many of the dispensable genes block host responses to infection. These responses may be effective in some cells but not others. Obvious examples of functional mimicry are the TK, ribonucleotide reductase, and so forth. The less obvious homologs are the cellular protein kinases (e.g., protein kinase A) that substitute for some of the viral enzymes (e.g., U_53). The complexity involved in defining the function of the numerous genes whose products are dispensable for viral replication in at least some cells in culture is offset by the fact that these genes are excellent probes of cellular functions. Once the riddle is solved, the answers can provide an unexpected wealth of information about both the virus and the host cell.

HERPES SIMPLEX VIRUS GENE FUNCTIONS LIST

This section summarizes the known gene products and their functions as an introduction to the sections dealing with viral replication and virus–host cell interactions. Although it is useful, the list has numerous limitations:

1. The list understates the number of the gene products. The HSV genome encodes a large number of ORFs with 50 or fewer codons, and not all of the ORFs have been probed to determine whether they are expressed. In addition, standard annotations exclude ORFs that are antisense to known ORFs or that do not have TATA boxes or other motifs that indicate that they encode proteins. HSV encodes several proteins whose ORFs are antisense to each other.
2. We have assigned a gene product designation to every transcriptional unit defined as giving rise to a specific RNA. Three points should be noted. First, HSV encodes numerous long noncoding RNAs and stable introns whose functions have not been thoroughly investigated. Examples are the large intron of ICP0, OriS RNA, and the recently reported U_55-1 RNA.⁵¹⁹ Second, several mRNAs are embedded inside and are 3' co-terminal with a large mRNA and encode a protein identical to the carboxyl terminal domain of the protein encoded by the larger mRNA. Examples include the $\alpha 22$

and $U_51.5$ transcripts, the U_53 and $U_53.5$ transcripts, and the U_{L26} and $U_{L26.5}$ transcripts. Lastly, transcripts arising late in infection frequently do not terminate at predicted termination signals.

3. There is an irresistible urge to classify proteins as essential or dispensable for replication, at least in some cells in culture. There are two limitations to this classification. The first is the definition of the cutoff value for essentiality. Is the protein essential if, in its absence, the yield is reduced by 10-fold, 100-fold, or 1,000-fold? A second limitation is that a specific protein may be essential in some cell lines but not others, or at high multiplicity but not at low multiplicity. For example, ICP0 is essential at low multiplicities of infection in most cells but not in U2OS cells. Notations of cell type restrictions are important in that they point to potentially important cellular functions that enhance or block viral functions.
4. Virtually all viral proteins studied in detail appear to perform multiple functions. Not all of the functions are known. In many instances, we do not fully understand the contribution of each function to the biology of the virus.
5. The descriptions of the ORFs and noncoding RNAs include their size as defined in the current reference sequence for HSV-1 strain 17. It should be noted that strain differences are common; thus, they should serve as a guide rather than as an absolute value.

Open Reading Frames

$\gamma_134.5$ (248 codons, γ_1 , nonessential). $\gamma_134.5$ encodes ICP34.5, which consists of two unequal domains linked by a variable number of alanine-proline-threonine repeats. The C-terminal domain is homologous to the C-terminal domain of GADD34 and functions as a phosphatase accessory factor, which binds phosphatase 1 α and redirects it to dephosphorylate the α subunit of the translation initiation factor 2 (eIF-2). In the absence of $\gamma_134.5$, protein kinase R is activated, eIF-2 α is phosphorylated, and all protein synthesis ceases. Loss of this function correlates with avirulence in animal models and humans. Another domain of $\gamma_134.5$ protein interacts with Beclin and blocks autophagy. The $\gamma_134.5$ protein plays a dual role in blocking both innate and adaptive immunity, the latter through evasion of major histocompatibility complex (MHC) class 2 responses.^{433,434,630,1157}

ORF-P (233 codons, pre- α , nonessential). ORF-P encodes the ORF-P protein, which binds p32 and localizes in spliceosomes. ORF-P is encoded on the strand complementary to $\gamma_134.5$. Transcription of ORF-P is blocked by ICP4 bound to a high-affinity site at the transcriptional initiation site of ORF-P. Derepression of ORF-P results in decreased expression of $\gamma_134.5$. Overexpression of ORF-P results in decreased expression of viral products of spliced RNAs.^{612,614}

ORF-O (117 codons, pre- α , nonessential). ORF-O encodes the ORF-O protein, which blocks the binding of ICP4 to its cognate high-affinity DNA binding sites *in vitro*. The N-terminus is identical to that of ORF-P. The amino acid sequence beyond residue 35 is in an alternate reading frame. Expression of ORF-O is repressed by ICP4.⁹¹⁶

$\alpha 0$ (775 codons, α , nonessential at high multiplicities). $\alpha 0$ encodes ICP0, an E3 ubiquitin ligase that promotes viral gene expression and inhibits host cell responses. The three exons encode a 775-residue protein containing a RING finger

domain. In transfected cells, it acts as a promiscuous transactivator of genes introduced by transfection or infection. Early in infection, it localizes near ND10 bodies. During this phase, it turns over with a half-life of approximately 1 hour. At late times, it accumulates in the cytoplasm. Several major interactions with cellular proteins have been reported. Thus, (a) it acts as a ubiquitin ligase, and in conjunction with UbcH5A ubiquitin conjugating enzyme, it degrades promyelocytic leukemia (PML) and SP100 proteins, resulting in dispersal of ND10 bodies. A consequence of the dispersal of ND10 bodies is loss of activation of antiviral genes by exogenous interferon (IFN). (b) ICP0 binds to CoREST (corepressor of the RE1 silencing transcript factor) and dissociates histone deacetylases (HDACs) 1 and 2 from the HDAC CoREST/LSD1/REST repressor complex. As a consequence, ICP0 blocks repression of viral genes by the repressor complex. (c) ICP0 also interacts with cyclin D3 to recruit CDK4 and with BMAL1 to recruit the CLOCK histone acetyl transferase (HAT) to the viral replication compartments. Additional functions have been described.^{181,400,401,402,409,526,527,644}

U_L1 (224 codons, γ_1 , essential). *U_L1* encodes glycoprotein L (gL), which chaperones gH (U_L22) through the Golgi to the plasma membrane. gL is not anchored to the plasma membrane and appears to regulate fusogenic activity of gH. It is conserved among herpesvirus subfamilies. gL is a target for neutralizing antibody.^{479,968}

U_L2 (334 codons, β or γ_1 , nonessential). *U_L2* encodes a uracil-DNA glycosylase enzyme, a highly conserved enzyme associated with the base excision repair pathway. Uracil-DNA glycosylase replaces uracil in G:U base pairs resulting from deamination of cytosine residues in DNA.^{156,1266}

U_L3 (235 codons, γ_2 , nonessential). *U_L3* encodes a nuclear non-structural protein of unknown function that is phosphorylated by the U_L13 protein kinase. U_L3 co-localizes with ICP22-U_S1.5 proteins in small dense nuclear structures. In the absence of ICP22 or U_S1.5, it is diffuse throughout the nucleus. The protein is translated predominantly from the second methionine of its reading frame. It interacts with ICP22 possibly through formation of complexes that include other proteins.^{51,714,1274,1277}

U_L4 (199 codons, γ_2 , nonessential). *U_L4* encodes a nuclear non-structural protein of unknown function. U_L4 co-localizes with ICP22/U_S1.5 in small dense nuclear structures formed prior to the onset of viral DNA synthesis. In the absence of other viral proteins, it remains in the cytoplasm. U_L4 forms complexes with other viral proteins.^{494,520,1277,1283}

U_L5 (882 codons, β , essential). *U_L5* encodes a component of the heterotrimeric helicase-primase complex that contains sequence motifs shared by members of the superfamily of RNA and DNA helicases. The U_L5-U_L52 complex has DNA-dependent adenosine triphosphatase (ATPase) and guanosine triphosphatase (GTPase), DNA primase, and DNA helicase activities. U_L5 function depends on its interactions with ICP8.^{282,414,1323}

U_L6 (676 codons, γ , essential). *U_L6* encodes the virion portal protein. U_L6, a putative leucine zipper protein, forms a dodecameric ring located at one vertex of the HSV capsid. U_L6 interacts with U_L15 and U_L28 (the putative terminase) proteins. Resistance to a class of thiourea drugs that block cleavage and packaging of DNA was mapped to the *U_L6* ORF.^{803,1236,1290}

U_L7 (296 codons, γ_1 , nonessential). *U_L7* encodes a virion tegument protein reported to interact with mitochondrial adenine nucleotide translocator 2.^{818,1125}

U_L8 (750 codons, β , essential). *U_L8* encodes the putative primase subunit of the heterotrimeric helicase primase complex and is required for the transport of U_L52 and U_L5 into the nucleus. It interacts with ICP8, U_L9, U_L30, and U_L42. It is required for unwinding of ICP8-coated DNA by ICP8.^{326,715,1134}

U_L8.5 (487 codons, γ_1 , unknown). *U_L8.5* encodes a protein corresponding to the C-terminal domain of U_L9 protein. It was reported to be synthesized both early and late in infection and to bind to the origin of DNA synthesis. In transient assays, the U_L8.5 protein inhibited DNA synthesis and may play a role in shifting the pattern of synthesis for *de novo* initiation at origins to a rolling circle model of viral DNA synthesis.^{60,61}

U_L9 (851 codons, β , essential). *U_L9* encodes the viral origin binding protein. U_L9 binds to specific sites flanking the origins of viral DNA synthesis. It acts as an ATPase and helicase and is required for initiation but not for continued DNA synthesis. hTid-1 enhances the binding of a multimer of U_L9 to the origin of DNA synthesis. NFB42, an F box component of SCF E3 enzyme binds phosphorylated U_L9 and targets it for ubiquitin-proteasomal degradation. The phosphorylation and degradation of U_L9 may enable the switch from *de novo* initiation of DNA synthesis at origins to a rolling circle type of DNA replication.^{314,569,628}

U_L9.5 (477 codons, γ_2 , unknown). *U_L9.5* encodes a protein of unknown function but may be the same as the U_L8.5 protein because the transcript of *U_L9.5* is co-terminal with those of *U_L8*, *U_L8.5*, and *U_L9*.⁶¹

U_L10 (473 codons, γ_2 , nonessential). *U_L10* encodes glycoprotein M (apparent M_r 53,000–63,000), predicted to contain six to eight transmembrane segments. It forms a complex with U_L49. Although a $\Delta gM\Delta gE$ HSV mutant showed no major impairment of growth, gM/U_L49.5 altered the localization and decreased the fusogenic activity of HSV glycoproteins.^{52,238}

U_L11 (96 codons, γ , nonessential). *U_L11* encodes a myristoylated, palmitoylated tegument protein of unknown function. ΔU_{L11} mutants exhibit reduced levels of envelopment and egress of virus from infected cells. The protein associates with lipid rafts, binds the cytoplasmic face of cellular membranes, and recycles to the Golgi. It is particularly abundant in the Golgi apparatus. U_L11 interacts with and directs U_L16 to the Golgi.^{53,581,677,698}

U_L12 (626 codons, β , nonessential). *U_L12* encodes an alkaline exonuclease that potentially functions as a resolvase, an enzyme required for processing of replication intermediates that would interfere with the packaging of viral DNA into capsids. It forms a complex with ICP8 that has recombinase activity.^{56,385,717,932}

U_L12.5 (~500 codons, nonessential). *U_L12.5* encodes a protein that corresponds to the C-terminal portion of the U_L12 protein. The protein accumulates in the cytoplasm, contains a mitochondrial localization signal, and degrades mitochondrial DNA.^{228,717,981}

U_L13 (518 codons, γ , nonessential). *U_L13* encodes a serine/tyrosine protein kinase enzyme that phosphorylates many viral and cellular proteins. It is present in the virion tegument;

- however, its function as a tegument protein is unknown. U_L13 appears to regulate multifunctional proteins and disrupt nuclear lamins. The kinase specificity of U_L13 is similar to that of *cdc2*.^{36,247,906,1064}
- U_L14** (219 codons, γ_2 , nonessential). U_L14 encodes a virion tegument protein. ΔU_L14 mutants replicate well in cell culture but are highly attenuated in the mouse. The only function attributed to U_L14 is enhancement of nuclear localization of U_L17 and U_L26 . Co-expression of U_L14 enhances nuclear import of the U_L35 (VP26) and U_L33 proteins and increases luciferase expression, suggesting that it may facilitate folding of various proteins. U_L14 has been implicated in cell-to-cell trafficking of virus.^{242,1284,1286}
- U_L15** (735 codons, γ , essential). U_L15 encodes a protein that binds U_L28 and U_L6 and is required for cleavage and packaging of viral DNA (terminase). The ORF consists of two exons. The intron is antisense to the U_L16 and U_L17 ORFs. The protein is cleaved at its N-terminus—a reaction coupled with maturation of viral DNA into unit-length molecules.^{49,235,988}
- $U_L15.5$** (293 codons, γ , unknown). $U_L15.5$ encodes a capsid-associated protein of unknown function from exon 2 of U_L15 .⁴⁹
- U_L16** (373 codons, γ_1 , essential). U_L16 encodes a tegument protein that interacts with the U_L11 and U_L21 proteins, and is encoded by a sequence antisense to the U_L15 intron. U_L16 dissociates from capsids on interaction with receptors.^{425,791,988}
- U_L17** (703 codons, γ , not essential). U_L17 encodes a putative tegument protein that plays a role in the terminal stages of DNA cleavage and packaging. This ORF is encoded in sequences antisense to exon 2 of U_L15 . In productive infection, U_L17 may localize preformed capsids to the replication compartment.^{986,987,1130}
- U_L18** (318 codons, γ_1 , essential). U_L18 encodes VP23 (M_r 34,000), a capsid protein that together with the VP19C (U_L38) forms triplexes consisting of two copies of VP23 and one copy of VP19C. The 320 triplexes connect adjacent hexons⁷⁰⁶ and pentons.^{53,1162}
- U_L19** (1,311 codons, γ_1 , essential). U_L19 encodes VP5 (M_r 149,000), the major capsid protein present in hexons that appear as tower-like complexes on the capsid in hexons and pentons.^{120,804,1265}
- U_L20** (222 codons, γ_1 , nonessential). U_L20 encodes a protein that is predicted to be polytopic with four predicted transmembrane segments. It localizes to virions, nuclear membranes, and Golgi but is absent from plasma membranes. When expressed singly, it localizes mainly to endoplasmic reticulum. Co-expressed with gK, it localizes to the Golgi and inhibits cell–cell fusion. A deletion mutant in the U_L20 gene is defective for transport of the virions out of the perinuclear space, particularly in cells with fragmented Golgi. The ΔU_L20 mutant is syncytial. Its postulated role is to prevent fusion of the infected cells with adjacent cells. U_L20 interacts with gK and gB.^{45,54,197,341}
- $U_L20.5$** (160 codons, γ_2 , nonessential). $U_L20.5$ encodes a protein of unknown function that localizes to small dense nuclear structures containing ICP22, $U_S1.5$, U_L3 , and U_L4 . The $U_L20.5$ ORF is located upstream of the U_L20 ORF.¹²¹⁸
- U_L21** (535 codons, γ , nonessential). U_L21 encodes a nucleotidylated tegument protein weakly associated with capsids. It binds to microtubules but not to purified tubulin. It binds U_L6 .^{48,98,1121}
- U_L22** (838 codons, γ , essential). U_L22 encodes glycoprotein H (gH), which is essential for virion infectivity and cell–cell fusion. In cells infected with a gH deletion mutant or a ts mutant at the nonpermissive temperature, viruses lacking gH egress from the cell but are not infectious. Transport of gH from the endoplasmic reticulum to the Golgi and plasma membranes requires the interaction with soluble gL. gH is an essential component of the complex enabling cell–cell fusion and induces neutralizing antibodies.^{271,340}
- U_L23** (376 codons, β , nonessential). U_L23 encodes the TK. Although known primarily as a TK, it is a wide-spectrum nucleoside kinase capable of phosphorylating both purine and pyrimidine nucleosides and their analogs. TK plays a crucial role in activating nucleoside analogs used for treatment of HSV infections.^{226,557,732}
- U_L24** (269 codons, γ_1 , nonessential). U_L24 encodes a membrane-associated nuclear protein (M_r 30,000). Mutant viruses defective for U_L24 form small polykaryocytes in cell culture, yield less virus, and exhibit decreased virulence in mice. U_L24 is associated with dispersal of nucleolin. Other functions remain to be determined. The U_L24 coding sequences are contained in six different mRNAs originating from three different initiation sites and terminating at two different 3' termination sites, and the synthesis and cytoplasmic accumulation of these transcripts is regulated by ICP27. The U_L24 ORF partly overlaps the *TK* gene on the opposite strand.^{89,419,692,857}
- U_L25** (580 codons, γ_2 , essential). U_L25 encodes a capsid protein involved in release of viral DNA after penetration and in capsid assembly after packaging of DNA and possibly for retention of DNA in the capsid.^{735,798,825}
- U_L26** (635 codons, γ , essential). U_L26 encodes a protease and scaffolding protein involved in capsid assembly. The U_L26 product is cleaved in *cis*- or *trans*- by itself at two sites: the N-terminal polypeptide being a serine protease required for assembly of a scaffolding within capsids for DNA packaging, and the larger, middle cleavage product a component of the scaffolding.^{657,658}
- $U_L26.5$** (326 codons, γ , essential). $U_L26.5$ encodes a protein that is identical to the C-terminal sequence of the U_L26 protein. The promoter and coding domain of the $U_L26.5$ gene is contained in its entirety within the U_L26 ORF. $U_L26.5$ is cleaved by the protease at its C-terminus at the same site as the U_L26 protein.⁶⁵⁸
- U_L27** (904 codons, γ_1 , essential). U_L27 encodes glycoprotein B (gB), which interacts with gH/gL and with gD is an essential step for entry by fusion of the envelope with the plasma membrane. Virions lacking gB egress the cell but are non-infectious. The protein binds heparan sulfate. Mutations in the cytoplasmic tail cause formation of syncytia. The tail also contains endocytosis motifs, which mediate gB endocytosis into large vacuoles. Down-modulation of gB by gK at cell surfaces may be responsible for negative control of cell–cell fusion. A ts mutation in the ectodomain (tsB5) affects virus entry into the cell. gB induces neutralizing antibodies. gB decorated by O-linked glycans interacts with the paired immunoglobulin (Ig)-like type 2 receptor α .^{29,144,196,441,859,998}
- $U_L27.5$** (undefined but not >575 codons, γ_2 , unknown). $U_L27.5$ encodes a cytoplasmic protein of unknown function with an

- apparent M_r of 43,000; its size is smaller than the predicted capacity of the ORF. The ORF maps antisense to *U_L27*.¹⁷⁷
- U_L28*** (785 codons, γ , essential). *U_L28* encodes a putative subunit of the terminase, a component of the DNA cleavage and packaging complex. It interacts with *U_L15*, *U_L6*, *U_L14*, and *U_L33*. *U_L28* binds *pac1* sequences and is required for correct generation of the L-terminus.^{76,492,1288}
- U_L29*** (1,196 codons, β , essential). *U_L29* encodes ICP8, the viral major DNA-binding protein, which unwinds and binds single-stranded DNA. ICP8 plays a key role in viral gene expression and an essential role in synthesis of viral DNA. ICP8 enables the unwinding of the DNA at the origin by *U_L9* and allows the entry of the machinery that replicates the DNA. ICP8 may also serve as a scaffold for organization of the replication complex. ICP8 in combination with *U_L12* or another nuclease has recombinase activity.^{188,221,932}
- U_L30*** (1,235 codons, β , essential), *U_L30* encodes the catalytic subunit of the viral DNA polymerase. The coding sequence is contained in several transcripts differing in size and temporal patterns of accumulation.^{104,1228,1229}
- U_L31*** (306 codons, γ , essential in a cell-type dependent fashion). *U_L31* encodes a nuclear protein required for viral disruption of the nuclear lamina and promotes primary envelopment at the inner nuclear membrane. *U_L31* requires *U_L34* protein for localization at the inner nuclear membrane and for its stability.^{98,179,935,1051,1295}
- U_L32*** (596 codons, γ_2 , essential). *U_L32* encodes a cysteine-rich, zinc-binding protein that is highly conserved among different herpesviruses and plays an essential role in the cleavage of concatemeric viral DNA into monomeric genomes and their packaging into preformed capsids. Localization of *U_L32* to the nucleus requires the presence of *U_L6*, *U_L25*, *U_L17*, and *U_L28*.^{178,619}
- U_L33*** (130 codons, γ_2 , essential). *U_L33* encodes a nuclear protein that along with *U_L6*, *U_L15*, *U_L17*, *U_L28*, and *U_L32* is required for packaging of viral DNA into preformed capsids. *U_L33* is reported to be translocated into the nucleus along with VP26 by *U_L14*.^{75,933,1286}
- U_L34*** (275 aa, γ_1 , essential). *U_L34* encodes a type 2 membrane protein phosphorylated by the *U_S3* kinase that localizes in nuclear membranes and is required for nuclear envelopment. *U_L34* is present in perinuclear virions but not in extracellular virions. Exclusive localization of *U_L34* protein at the nuclear membrane requires *U_L31* in certain cells.^{907,935,1035,1285}
- U_L35*** (112 codons, γ_2 , nonessential). *U_L35* encodes the VP26 capsid protein, which forms a hexameric structure located on the outer surface of each hexon. It interacts with dynein light chains RP3 and Tetex1 and is involved in intracellular transport.^{215,267,289}
- U_L36*** (3,165 codons, γ_2 , essential). *U_L36* encodes a tegument protein designated VP1-2 (M_r >270,000), the largest protein encoded by HSV. It is required for egress of virions through the cytoplasm. A ts mutation in *U_L36* (*tsB7*) blocks release of viral DNA into the nucleus at the nonpermissive temperature. Release of DNA requires proteolytic cleavage of the protein. Late in infection, cells contain a truncated protein consisting of the amino-terminal domain that exhibits a cysteine protease deubiquitinating activity. *U_L36* and *U_L37* form tufts of elongated strands at the vertices of capsids.^{73,270,518,534,796,1008}
- U_L37*** (1,123 codons, γ_1 , essential). *U_L37* encodes a tegument phosphoprotein that binds to DNA in the presence of ICP8. In the absence of *U_L37*, nucleocapsids accumulate aberrantly in the nucleus and unenveloped capsids accumulate in the cytoplasm. The protein interacts with VP1-2 (see *U_L36*).¹⁰¹³
- U_L38*** (465 codons, γ_2 , essential). *U_L38* encodes the capsid protein VP19C. This protein forms triplexes consisting of two copies of VP23 (*U_L18*) and one copy of VP19C. The 320 triplexes connect adjacent hexons and pentons.^{1082,1162}
- U_L39*** (1,137 codons, β , nonessential). *U_L39* encodes ICP6, which is the large subunit of ribonucleotide reductase. ICP6 is anchored in membranes and has protein kinase activity mapping to the N-terminus; however, this is not required for ribonucleotide kinase activity. *U_L39* may play a role in maintaining dTTP pools in infected cells.^{202,248,862}
- U_L40*** (340 codons, β , unknown). *U_L40* encodes the small subunit of ribonucleotide kinase.⁴⁸⁶
- U_L41*** (489 codons, γ_1 , nonessential). *U_L41* encodes a tegument protein with an endoribonuclease activity with a substrate specificity similar to that of ribonuclease A (RNase A). This is termed the VHS function and protein. VHS introduced into cells during infection degrades (a) stable mRNAs in polyribosomes from 5' to 3' and (b) mRNAs containing A-U-rich elements by deadenylation and endonucleolytic cleavage in the 3' untranslated region (UTR). Other features suggest that the degradation of mRNA is selective. Newly made VHS is neutralized by VP16 (*U_L48*) and VP22 (*U_L49*). VHS also interacts with ICP27.^{317,1022,1105,1116,1118,1120}
- U_L42*** (488 codons, β , essential). *U_L42* encodes the DNA polymerase processivity factor, which binds double-strand DNA and tethers the polymerase to its template and increases its processivity. *U_L42* also associates with cdc2 and topoisomerase II α .^{11,389}
- U_L43*** (434 codons, γ , nonessential). *U_L43* encodes a hydrophobic, myristoylated integral membrane protein of unknown function.^{161,699}
- U_L43.5*** (91 codons, γ_2 , nonessential). *U_L43.5* encodes a hydrophilic protein localizing in nuclear structures containing capsid proteins. The ORF is encoded antisense to *U_L43*.¹²¹⁷
- U_L44*** (511 codons, γ_2 , nonessential). *U_L44* encodes glycoprotein C (gC), which mediates attachment of virions to cells by binding to glycosaminoglycans of heparan sulphate or to chondroitin sulfate to a site near its N-terminus. Δ gC mutants attach to cells with reduced efficiency. gC contains two domains involved in modulating complement activation: one binds C3, and the other is required for blocking C5 and properdin binding to C3. Each region contributes to virulence, as viruses lacking these domains are less virulent than wild-type virus. gC is heavily N- and O-glycosylated.^{354,443,685}
- U_L45*** (172 codons, γ_2 , nonessential). *U_L45* encodes a type II membrane protein of unknown function.^{286,1192}
- U_L46*** (718 codons, γ_1 , nonessential). *U_L46* encodes tegument proteins VP11 and VP12, differentiated solely by their migration in denaturing gels. VP11-12 associates with capsids and membranes, binds VP13-14 (*U_L47*) in stoichiometric amounts with VP16 (*U_L48*), and enhances the latter's activity. In the absence of *U_L48* protein, *U_L46* inhibits activation of α promoters. VP11-12 is stabilized by *U_S3* kinase and activates Lck kinase.^{66,720,731,778,1200,1201,1311}

U_L47 (693 codons, γ_1 , nonessential). *U_L47* encodes the VP13 and VP14 tegument proteins, which along with *U_L46* enhance the activity of VP16 (*U_L48*). *U_L47* in conjunction with ICP27 binds and displaces PABC1 from the poly(A)-binding protein (PABP) binding complex on the cap structure. It is reported to shuttle between the cytoplasm and nucleus.^{66,98,279,287,744,1023}

U_L48 (491 codons, γ , essential). *U_L48* encodes VP16 or (α -trans-inducing factor (α -TIF), a multifunctional tegument protein. It induces α genes by interacting with two cellular proteins, HCF and Oct-1. The complex binds to specific sequences with the consensus GyATGnTAAT-GArATTCy-NC. It is also required for virion assembly. Together with VP22 (*U_L49*), it interacts with and blocks the ribonuclease (RNase) activity of *U_L41*.^{665,695,860,1158}

U_L49 (301 codons, γ_2 , nonessential). *U_L49* encodes the VP22 tegument protein, which binds RNA and translocates it from infected to adjacent, noninfected cells. It has been shown to interact with chromatin remodeling proteins and to block nucleosome assembly in transfected cells. It binds to microtubules and after cell division to chromatin. It has also been reported to bind membranes and to induce the stabilization and hyperacetylation of microtubules (putative microtubule-associated protein). It is not required for tegument assembly; however, it plays a critical role in neutralization of VHS. Mutants lacking VP22 express a defective VHS.^{98,123,882,1022,1023,1180}

U_L49.5 (91 codons, γ_2 , essential). *U_L49.5* encodes the gN membrane-associated protein with apparent *M_r* of 6700 that is abundant in virions. It interacts with gM (*U_L10*), and gM may be required for packaging of *U_L49.5* in virions. Reported to block endogenous antigen presentation.^{6,67,831}

U_L50 (371 codons, β , nonessential). *U_L50* encodes a monomeric deoxyuridine 5'-triphosphate nucleotidohydrolase (dUTPase).^{57,66}

U_L51 (244 codons, γ_2 , nonessential). *U_L51* encodes a tegument protein that localizes to the Golgi apparatus and is involved in virus egress.^{66,246,819}

U_L52 (1,058 codons, β , essential). *U_L52* encodes the primase subunit of the HSV helicase-primase complex. Its strongest affinity appears to be for ICP8; however, both *U_L8* and *U_L5* proteins are required for DNA binding.^{95,291,558}

U_L53 (338 codons, γ , nonessential). *U_L53* encodes glycoprotein K (gK), whose sequence predicts three transmembrane segments. Epitope mapping predicts an extracellular N-terminus and intracellular C-terminus. In infected cells, gK localizes to the Golgi apparatus. In transduced cells, gK localizes mainly in the endoplasmic reticulum (ER). Colocalization with Golgi markers requires the *U_L20* protein. Plasma membrane localization is less clearly defined. gK is the most frequent locus of syncytial (syn) mutations. A Δ gK mutant virus is defective in virion exocytosis and is syncytial. gK inhibits fusion in the cell-cell fusion assay. Inhibition is augmented by co-expression with *U_L20* protein. One function of gK may be to prevent infected cells from fusing with adjacent cells.^{45,342,480,496,880}

U_L54 (512 codons, α , essential). *U_L54* encodes the ICP27 multifunctional regulatory protein. Early in infection, its major role is to block pre-mRNA splicing and thus contributes to the shutoff of host protein synthesis. At the same time, and particularly at late times after infection, ICP27 is required

for transcription of some β and γ_1 , and perhaps all γ_2 genes. Thus, ICP27 recruits cellular RNA polymerase II (pol II) to the viral genome to promote efficient viral transcription. It shuttles between nucleus and cytoplasm, promoting the cytoplasmic accumulation of some mRNAs. It is intimately involved in translation. It binds RNA and interacts with numerous cellular and viral proteins.^{98,245,313,339,497,995,1314}

U_L55 (186 codons, γ_2 , nonessential). *U_L55* encodes a nonstructural protein of unknown function that is associated with sites of virion assembly.¹²⁸²

U_L56 (234 codons, γ_2 , nonessential). *U_L56* encodes a phosphorylated type II virion membrane protein. It was reported to interact with and relocalize a member of the Nedd4 family of ubiquitin ligases and to bind kinesin motor protein KIF1A. It was reported to be required for pathogenesis in mice.^{579,580,970,1177}

$\alpha 4$ (1,298 codons, α , essential). $\alpha 4$ encodes ICP4, a protein that acts as a repressor and as a transactivator of viral transcription. As a repressor, it binds to high-affinity sites overlapping the transcription initiation sites of its own gene and that of ORF-P and ORF-O. It also interacts with cellular transcription factors (e.g., TFIID) and is present in transcriptional complexes containing ICP22, ICP27 and the CLOCK HAT, and with DNA at low-affinity sites whose sequences are significantly different from that of high-affinity sites. The interaction of ICP4 together with transcription factors at low-affinity sites may account for the transactivating function of ICP4. The role of low-affinity sites remains unclear.^{264,394,526,843}

$\alpha 22/U_S1$ (420 codons, α , nonessential). $\alpha 22/U_S1$ encodes the ICP22 regulatory protein, which is required in experimental animal systems and some nonhuman cell lines but not in Vero or HEp-2 cells. The properties encoded in its C-terminal domain are similar to those of *U_S1.5* described later and are principally manifested by reduced accumulation of a subset of γ_2 genes. Deletion of the entire ORF exacerbates the attenuation phenotype. The protein is extensively phosphorylated by viral and cellular kinases and nucleotidylated by casein kinase II. Thus, in the absence of ICP22 or *U_L13*, a set of late proteins (*U_L41*, *U_S11*, and *U_L38*) accumulates in smaller amounts. Both ICP22 and *U_L13* are required for the activation of *cdc2* and degradation of the partners, cyclin A and B. *cdc2* partners with *U_L42* and together bind and mediate postranscriptional modification of topoisomerase II α . These steps are essential for optimal expression of *U_L41*, *U_S11*, and *U_L38*. *U_L13* and ICP22 mediate the phosphorylation of the C-terminal domain of RNAi pol II. In addition, ICP22 interacts with *cdk9* in a *U_S3* kinase-dependent fashion to phosphorylate RNAi pol II. ICP22 also affects the accumulation of $\alpha 0$ mRNA. ICP22 and the *U_L13* protein kinase mediate the degradation of cyclin B. *cdc2* acquires a new partner—the *U_L42* polymerase accessory factor—and together they recruit topoisomerase II to enable the expression of the subset of γ_2 genes exemplified by *U_L41*, *U_S11*, and *U_L38*. It has been detected in complexes containing ICP4, ICP27, TFIID, and CLOCK HAT.^{11,304,526,673,757}

U_S1.5 (250 codons, α , nonessential). *U_S1.5* is expressed from a promoter and coding domain contained within the $\alpha 22$ ORF, and the $\alpha 22$ methionine 171 codon acts as the initiator codon of the *U_S1.5* ORF. Most of the known functions of ICP22 map to the *U_S1.5* ORF.^{11,159,675}

U_S2 (291 codons, γ_2 , nonessential). *U_S2* encodes a tegument protein reported to interact with cytokeratin 18.^{388,506}

U_S3 (481 codons, γ_1 , nonessential). *U_S3* encodes a multifunctional serine-threonine protein kinase that phosphorylates HDAC1 and 2, CoREST, U_L34, and a host of other viral and cellular proteins. Its substrate specificity is similar to that of cellular protein kinase A. It promotes egress of capsids from nuclei and is essential for blocking apoptosis induced by viral or exogenous inducers. A key function of the *U_S3* protein kinase is to alter the structure of nuclear membranes so as to enable budding of capsids into the lumen between the inner and outer nuclear membranes.^{82,639,907,977}

U_S3.5 (405 codons, γ_1 , nonessential). *U_S3.5* encodes a truncated *U_S3* protein kinase enzyme initiated at the *U_S3* methionine 71 codon on an mRNA that is smaller than that encoding *U_S3*. *U_S3.5* mediates the phosphorylation of HDAC1 and does not block apoptosis.⁸⁸⁶

U_S4 (283 codons, γ_1 , nonessential). *U_S4* encodes glycoprotein G (gG), whose precise function is not known; it has been shown to bind to chemokines.¹¹⁹¹ The HSV-2 gG is larger than HSV-1 gG; thus, gG can be used to differentiate HSV-1 from HSV-2 antibody responses.^{3,626}

U_S5 (92 codons, γ , nonessential). *U_S5* encodes glycoprotein J (gJ), which blocks apoptosis induced by granzyme B, Fas, or by infection of cells with glycoprotein D (gD; *U_S6*) minus viruses and other agents.^{501,1316}

U_S6 (394 codons, γ , essential). *U_S6* encodes gD, a multifunctional protein with the following properties: (a) it interacts with three cellular receptors for entry—HvE, nectin1, and a modified heparin sulfate; hence, it defines viral tropism. (b) Upon receptor binding, an ensuing change in conformation exposes fusion domains that enable the fusogenic glycoproteins gB, gH, and gL to complete fusion of the envelope with the plasma membrane. (c) The N-terminal domain may be replaced with ligands for entry via other receptors. (d) gD protects the cell from apoptosis induced by Δ gD mutants. Antiapoptotic activity is mediated by mannose-phosphate receptor. (e) Δ gD mutants grown in cells ectopically expressing gD produce virions that exit the cell but are noninfectious.^{157,209,368,1131,1316}

U_S7 (390 codons, γ_1 , nonessential). *U_S7* encodes glycoprotein I (gI), which forms a heterodimer with gE. The gE-gI complex constitutes a viral Fc receptor for monomeric immunoglobulin G (IgG). The gE-gI complex has basolateral localization in epithelial cells and facilitates basolateral spread of progeny virus in polarized cells. *U_S7* is dispensable in transformed cells but critical in nontransformed cells.^{277,508,674}

U_S8 (550 codons, γ_1 , nonessential). *U_S8* encodes glycoprotein E (gE), the major component of the viral Fc receptor. It is phosphorylated by the U_L13 kinase and forms a heterodimer with gI (*U_S7*). *U_S8* has been implicated in cell-to-cell spread and in virion transport in neurons and antihost defenses.^{74,277,686,1212}

U_S8.5 (159 codons, γ_1 , nonessential). *U_S8.5* encodes a nuclear protein of unknown function that localizes to nucleoli. Its mRNA is among the most abundant species packaged in virions.^{367,675,1023}

U_S9 (90 codons, γ , nonessential). *U_S9* encodes a type II membrane-associated protein. *U_S9* may play a role in axonal spread.^{675,728,814,1066}

U_S10 (312 codons, γ_1 , nonessential). *U_S10* encodes a tegument phosphoprotein of unknown function that co-purifies with the nuclear matrix.^{675,814,1281}

U_S11 (161 codons, γ_2 , nonessential). *U_S11* encodes an RNA-binding protein with multiple functions: (a) it binds RNA in sequence- and conformation-dependent fashion and is in part responsible for the packaging of RNA in virions. Virion-associated *U_S11* binds to ribosomes and localizes to polyribosomes. (b) When expressed from an early promoter, it blocks activation of protein kinase R. (c) Late in infection, *U_S11* is also found in nucleoli. (d) *U_S11* interacts with and blocks homeodomain-interacting protein kinase 2 (HIPK2).^{165,379,675,887,963,1023}

α 47/*U_S12* (88 codons, α , nonessential). α 47/*U_S12* encodes ICP47, which selectively binds to human TAP1/TAP2 and blocks the transport of antigenic peptides into the ER for presentation at the cell surface.^{446,723,1152,1302}

Noncoding RNAs

LAT. The primary LAT is a low-abundance transcript of 8.5 to 9 kb in size and extends through the length of the *ab* and *b'a'* sequences flanking the unique long sequences. The smaller LATs are stable introns and terminate antisense to and within the coding sequences of the α 0 gene. Deletion of the sequences encoding LAT increases the mortality and morbidity in experimental animal systems and decreases the number of neurons harboring latent virus. The decrease in the number of neurons in LAT minus mutants has been linked to increased viral gene expression and pro-apoptotic manifestations of latent virus. The LAT promoter has neuron-specific elements. Accumulation of LAT correlates with increased assembly of viral DNA into heterochromatin.^{206,329,360,866,1101,1214}

ORI_S RNAs. These 5' co-terminal RNAs originate in the *c* sequences flanking the unique short sequences at or near the transcription initiation sites of the α 22 or α 47 genes. Ori_{S1} is synthesized early in infection in the absence of protein synthesis and runs antisense to α 22 or α 47 genes, terminating at the transcription initiation sites of these genes. Ori_{S2} extends across the ORI_S sequence and co-terminates with the transcript encoding ICP4. The HSV-1 Ori_{S2} contains an ORF, whereas the HSV-2 Ori_{S2} does not. Ori_{S2} RNA is detected late in infection. The function of these RNAs is not known.⁴⁷⁶

α X and β X RNAs. These overlapping RNAs are 0.9 and 4.9 Kb in size, originate upstream of ORF P, and extend across the L-S junction. Their function is not known.^{108,644}

AL-RNA. Reported to be antisense to the 5' sequences of LAT.⁸⁶⁸

α 0 Intron 1 RNA. This is a family of four RNAs with a common 5' end but differing 3' sequences. The RNAs are stable, nonpolyadenylated, and accumulate in the cytoplasm. Their functions are not known.¹⁶⁰

***U_S5–1* RNA.** The RNA initiates in *U_S5* and terminates in the α 22 ORF. It is expressed antisense to *U_S5*, *U_S4*, *U_S3*, and ICP22 mRNAs. This transcript is expressed with γ 2 kinetics and has a half-life of 80 minutes. There is no evidence that it encodes a protein.⁵¹⁹

MicroRNAs. MicroRNAs have been detected in trigeminal and sacral ganglia of mice latently infected with HSV-1

and HSV-2, respectively. The microRNAs are largely derived from the genome domains encoding the LAT precursor RNA. To date, no evidence has emerged that the microRNAs play a defined role in the establishment or maintenance of latency.^{240,521,1126,1169,1170}

VIRAL REPLICATION

Overview of Herpes Simplex Virus Replication

It is convenient to begin this section on viral replication with a bird's eye view of the major events of HSV replication (Fig. 60.3).

To initiate infection, the virus must attach to cell surface receptors. Fusion of the envelope with the plasma membrane or an internal membrane rapidly follows the initial attachment.

The de-enveloped tegument-capsid structure is then transported to the nuclear pores, where DNA is released into the nucleus.

Transcription of the viral genome, replication of viral DNA, and assembly of new capsids take place in the nucleus. Viral DNA is transcribed throughout productive infection by host RNA pol II, but with the participation of viral factors at all stages of infection. The synthesis of viral gene products is tightly regulated: Viral gene expression is coordinately regulated and sequentially ordered in a cascade fashion. The gene products studied to date form at least five groups (α , β_1 , β_2 , γ_1 , and γ_2) as a result of both transcriptional and posttranscriptional regulation. The α or immediate-early genes are expressed first and are defined as the genes that are transcribed in the absence of *de novo* viral protein synthesis. The α gene products are involved in activating expression of the β or delayed-early genes. Several of the β gene products are enzymes and

FIGURE 60.3. Diagram of the replication cycle of herpes simplex virus. 1: The virus binds to the cell plasma membrane and the virion envelope fuses with the plasma membrane (1a) or the virus enters by endocytosis (1b), releasing the capsid and tegument proteins into the cytoplasm. 2: The capsid is transported to the nuclear pore, where the viral DNA is released into the nucleus. 3: The vhs protein causes degradation of host messenger RNAs (mRNAs). 4: VP16 localizes into the nucleus. 5: The viral DNA circularizes. 6: It is then transcribed by host RNA polymerase II to give first the α mRNAs. α gene transcription is stimulated by the VP16 tegument protein. Five of the six immediate-early proteins act to regulate viral gene expression in the nucleus. 7: α proteins transactivate β gene transcription. 8: The β proteins are involved in replicating the viral DNA molecule. 9: Viral DNA synthesis stimulates γ gene expression. 10: The γ proteins are involved in assembling the capsid in the nucleus and modifying the membranes for virion formation. 11: DNA is encapsidated in the capsid. 12: The filled capsid buds through the inner membrane to form an enveloped virion, and the virion exits from the cell by mechanisms described in the text. (Copyright Lynne Chang and David Knipe.)

FIGURE 60.4. Replication compartments in the nuclei of herpes simplex virus (HSV)-infected cells. Shown are Vero cells infected with HSV-1 strain KOS virus and fixed at 7 hours postinfection and stained with anti-ICP8 antibody (green) to mark replication compartments and anti-lamin B1 antibody (red) to mark the nuclear lamina and define the boundaries of the nucleus. The punctate structures containing ICP8 within the larger globular replication compartments co-localize with sites of viral DNA synthesis. (Copyright Lynne Chang and David Knipe.)

DNA-binding proteins involved in viral DNA replication in nuclear replication compartments (Fig. 60.4). The bulk of viral DNA is synthesized by a rolling circle mechanism, yielding concatemers that are cleaved into monomers during the process of nucleocapsid assembly. The γ or late genes are then transcribed efficiently following viral DNA replication, and these gene products are largely involved in assembly of the progeny virions.

Assembly occurs in several stages. After packaging of DNA into preassembled capsids, the filled capsid or nucleocapsid matures into a virion and acquires infectivity by budding through the inner lamella of the nuclear membrane. The transit of virions from the space between the inner and outer nuclear membranes to the subcellular space is less well defined. It has been suggested that the virion envelope is processed by transit through Golgi stacks, by being de-enveloped and then re-enveloped at the trans Golgi network, or by the nucleocapsid exiting the nucleus through nuclear pores and then budding into the Golgi apparatus. In fully permissive tissue culture cells, the entire process takes approximately 18 to 20 hours.

HSV infection reorganizes the host cell in many ways, some of which have only recently been discovered. HSV causes extensive reorganization of cell structure, with nuclear changes including margination of chromatin, enlargement of the cell nucleus, formation of replication compartments, disruption of the nuclear lamina and nucleoli, and cytoplasmic changes including disruption of the Golgi apparatus and microtubules.⁹⁵⁶ It was recently discovered that HSV infection alters cellular metabolism, in part by diverting the central carbon metabolism toward the production of pyrimidine nucleotide components.¹¹⁸⁸ The study of the metabolomics of

HSV-infected cells will be an important new field for the next few years.

Entry of Herpes Simplex Virus

Pathways of Herpes Simplex Virus Entry Into Cells

Early electron microscope studies by Epstein led to the conclusion that entry of virus into cells occurs by fusion of the envelope with the plasma membrane. Fusion at the plasma membrane has been well documented for Vero and HEp-2 cells^{808,1270} and primary neurons.⁶⁹⁰ In contrast, although the presence of enveloped virus particles in the cytoplasm after exposure to the virus was reported approximately 40 years ago by Hummeler et al.⁴⁷⁷ and others,⁹⁵² it is only recently that entry by endocytosis became accepted as a significant pathway of entry for productive infection. HSV enters via endocytosis in other cell types such as Chinese hamster ovary (CHO) and HeLa cells.^{752,807,808} In turn, the endocytic pathway may be through acidic endosomes in some cells and through neutral endosomes in other cells,^{752,807,809} although the same viral glycoproteins are required for both pathways.⁸⁰⁹ Thus, whether HSV enters by fusion at the plasma membrane or following endocytosis is a cell line- or cell-type-dependent phenomenon. The cellular molecules that can serve as determinants of the pathway of entry into cells have come to light only recently. One such determinant appears to be $\alpha_3\beta_3$ -integrin. Thus, HSV-1 enters CHO cells by an endocytic pathway. In the absence of $\alpha_3\beta_3$ -integrin, the entry is by an endocytic pathway independent of lipid rafts and dynamin 2. Expression of $\alpha_3\beta_3$ -integrin in CHO cells routes HSV-1 to entry by an endocytic pathway dependent on lipid rafts and dynamin 2.³⁷² The properties of the gD receptor additionally contribute to determine the route of entry. Thus, entry into CHO cells via nectin is by lipid-raft-independent endocytosis. When nectin is modified and redirected to lipid rafts, entry is through lipid-raft-dependent endocytosis.

The endocytic pathway may well be the default entry pathway in certain situations. For example, in the absence of gD-receptor interactions, virions are taken up by endocytosis but are then degraded by lysosomal enzymes. Specifically, cells expressing gD take up wild-type virus in endocytic vesicles. Electron micrographs showed that the virions were rapidly degraded, and viral DNA could no longer be recovered after several hours.¹⁴⁸ gD^{-/-} mutants (i.e., virus stocks lacking both the gD gene and gD in their envelopes) are taken up by endocytosis and degraded by lysosomal enzymes. At high multiplicities gD^{-/-} virions induce apoptosis as defined by laddering of cellular DNA and other assays.¹³¹⁶

Attachment to the Cell Surface

Entry of HSV into cells involves the interaction of at least five virion surface glycoproteins with several molecules (receptors) on the cell surface and is the consequence of fusion of the envelope with a cellular membrane. The first step in the process of entry is the binding of virions to glycosaminoglycans (GAGs) on the cell surface. The interaction of virions with GAGs is mediated by two glycoproteins: gC and gB. Removal of GAGs from the cell surface or site-specific mutagenesis of gC and gB to disable the interaction with GAGs reduces virus yields by 10- to 20-fold. The available data suggest that GAGs serve as anchors or platforms from which virions interact with entry receptors. The hypothesis that the interaction of GAGs with virions is fully reversible has not been tested adequately.

The second step varies depending on the nature of the surface of the cells to which the virions are attached. Irrespective of the pathway of entry—endocytosis or fusion at plasma membrane—entry requires at the very least the interaction of virion glycoprotein gD with its receptors.

Interaction of Glycoprotein D With Its Receptors

The next series of steps in virus entry consists of the interaction of gD with its receptors and execution of fusion between the envelope and the cellular membrane by the heterodimer gH/gL and gB. The interaction of gD with its receptors has been extensively studied in many laboratories. The consensus is that, for entry, gD interacts with one of three natural receptors. The receptors are nectins, a protein designated as herpesvirus entry mediator (HVEM), and a selected form of 3-O-sulfated heparan sulfate (3-OS HS).^{150,209,368,765,1044,1077,1220} Nectin and HVEM are found on cells of numerous types and tissues, and this readily explains the ability of HSV to infect many seemingly diverse cells.

Nectins are intercellular adhesion molecules expressed on epithelial and neuronal cells, and are members of the extended Ig family. The N-terminal domains of a nectin dimer on the surface of one cell forms *trans*-dimers with the corresponding domains of nectins on adjacent cells. The C-terminal domains embedded in the cytoplasm interact with afadin, which in turn anchors the nectins to cytoskeleton.⁹⁸³ Earlier studies showed that gD of HSV-1 interacts with the amino-terminal V1 domain of nectin 1. This domain includes two loops—C-C' and C'-C"—and both loops play a role in the interaction with gD essential for virus entry.²⁰⁸ Recently, the crystal structure of gD bound to nectin 1 has extended earlier studies. Phenylalanine 129, at the tip of the loop connecting β -strands F and G of nectin 1 binds to the gD core.²⁷⁵ HSV-1 strains with specific mutations in gD and wild-type HSV-2 can also enter cells via nectin 2. The binding site on gD for with nectin 1 is complex and includes amino acid residues 34, 38, and 215 through 218.^{222,705}

HVEM is a member of the extended tumor necrosis factor (TNF) receptor family, expressed mainly by T lymphocytes,⁷⁷⁶ which in turn binds the lymphotoxin β receptor. Its natural ligand is LIGHT (homologous to lymphotoxins, exhibits inducible expression, and competes with HSV gD for HVEM, a receptor expressed by T lymphocytes), which is constitutively expressed on T and natural killer (NK) cells and appears to be a regulator of mucosal immune system.²¹⁴ The functional and structural interactions of HVEM to gD have been mapped to

the N-terminal residues 7 through 31 of gD,¹⁵⁷ a region of gD that can be deleted.¹³⁰¹

The third receptor, 3-OS HS, results from modification of HS by the HS 3-O-sulfotransferase. This enzyme is present in the brain and led to speculation that this receptor may play a role in that organ.¹⁰⁴⁴ However, little is known of the role played by this receptor in the natural history of HSV infection and of the mechanism of entry into cells via this receptor.

The sequence of events subsequent to the interaction of gD with its receptors has been postulated as follows. The conformation of gD is altered in a specific manner by its interaction with any of its receptors. The consequence of the conformational change is changes to gH and gL, and ultimately activation of gB, which enables the fusion of the envelope with the cellular membranes.

There are several issues regarding the interaction of gD with its receptors that need to be resolved. The role of each of these receptors in human infection remains to be defined. In genital infection of mice by HSV-2, knockout of HVEM has little effect on infection, whereas knockout of nectin 1 attenuates infection but does not entirely prevent infection of the central nervous system (CNS).¹¹³¹ By the intracranial route of infection, nectin 1 is required for infection and the ensuing encephalitis.⁵⁷⁷

Perhaps the key issue is the exact function of gD in fusion. Crystallographic and functional studies have defined several domains in gD.^{157,275,1308} These are an N-terminal domain containing the bulk of the binding sites for HVEM, an Ig-folded core (residues 56–184) and a profusion domain (residues 260–316) required for fusion with the cellular membranes (Fig. 60.5). The crystallographic studies on truncated soluble forms of HSV-1 gD suggest that the N-terminal domain and the core fold over the C-terminal portion of the soluble form, N terminal to residue 260, and that the unliganded gD adopts a closed conformation. Interaction of gD with its receptor changes the conformation of the gD. This process presumably activates gH/gL and gB, which will be addressed later.

A linear schematic representation of the monomeric form of gD is shown in Figure 60.5. Residues 1 through 38 are dispensable and can be replaced by a heterologous ligand for a novel receptor (e.g., interleukin [IL]-13 for IL-13 α 2, urokinase plasminogen activator for its receptor, or a single-chain antibody), and residues 61 through 218 can also be replaced. In this instance, the 158 residues comprising the Ig-folded domain were replaced with a single-chain antibody against HER-2 containing 268 residues. In each instance, the modified virions

FIGURE 60.5. Diagram of the domain structure of glycoprotein D. Shown are the residues required for nectin binding, the HVEM binding site, the profusion domain, and the immunoglobulin folded domain.

entered cells through the novel receptor. To further confound the issues, a recombinant virus (R5322), in which the wild-type gD was replaced with two independently expressed polypeptides, enters cells via the urokinase plasminogen activator. In this instance, the first polypeptide consisting of the signal peptide of gD, the amino terminus of the urokinase plasminogen activator fused to the peptide comprising the residues 32 to 60, formed a heterodimer with the independently expressed polypeptide containing residues 219 to the C terminus of gD. The expectation that each of the novel ligands on interaction with their cognate receptors provokes an identical conformational change in gD makes little sense.

The fundamental problem stems from two assumptions. The first is that the transmembrane and cytoplasmic domains pose no restrictions on the conformation adopted by gD. The crystallographic studies by necessity were restricted to the ectodomain, and simulation of the gD homodimer was done by synthetically engineering a homodimer consisting of ectodomains. The notion that the transmembrane and cytoplasmic domains are merely anchors and that higher order structures are not functionally required is belied by the observation that they do in fact play a role in the life cycle of the virus. In studies designed to define the regions of gD necessary to block apoptosis induced by endocytosed virus lacking the gD gene, the minimally effective gD construct is a complex consisting of two components: the ectodomain and transmembrane domain of gD, and the transmembrane and cytoplasmic domain of the same protein. Substitutions of the cysteine residue in the transmembrane domain of either component of the complex abolish the antiapoptotic activity of gD. The observation that such heterodimers arise spontaneously in transduced cells is a strong indication that homodimers could also arise by a similar mechanism. Parenthetically, a low-resolution, three-dimensional structure obtained with the aid of electron microscopy predicts that gD has a homotetrameric structure.⁸⁷⁶

The second assumption is more insidious and independent of the first. Regardless of the interaction of gD with its receptor, the fusion assays are done on intact cells. If the interaction of virions with GAGs were neutral (i.e., do not result in modification of the virion surface), the rate of random collisions between virions and gD receptors should not be affected by presence of or absence of GAGs. One possible explanation for the reduced infectivity of viruses lacking ability to bind to GAGs or on exposure of wild-type virus to cells from which GAGs have been removed is that to interact with GAGs, gB and gC must project from the surface of the virion. The interaction of gB and gH/gL may introduce conformational changes in these proteins as well as gD. In essence, it is conceivable that the postulated conformational changes following exposure to receptor are in fact effected by GAGs. The role of gD with respect to gB and gH/gL is to recruit them and position them properly to enable interaction with GAGs and the lipid bilayers of the cellular membranes and summarized elsewhere.^{560a}

Roles of Glycoprotein B and Glycoprotein H/Glycoprotein L

Studies on the roles of gB and gH/gL remain the focus of numerous laboratories; however, the roles they play in the entry process are less contentious. Crystallographic studies of the ectodomain of gB showed that it was structurally homologous to the vesicular stomatitis virus (VSV) glycoprotein (G).⁴⁴¹ The

solved structure for gB shows a trimer with an α -helical coiled-coil core, which related gB to class I viral membrane fusion glycoproteins, and a domain carrying two extended β hairpins with hydrophobic tips, homologous to fusion peptides in VSV G, which related gB to class II fusion proteins. Because of this new structure, gB was defined as a class III fusion protein (see Chapter 3). Both class I and class II fusion proteins undergo conformational changes to carry out fusion of the virion envelope bilayer with that of the cellular membrane; therefore, it is likely that gB also promotes fusion through this same process. A recent study showed that the pH-dependent change in gB was a local change.¹⁰⁸⁸ gB has been shown to bind to the paired immunoglobulin-like type 2 receptor- α (PILR α) to trigger viral fusion in certain cell types⁹⁹⁸; however, the precise role of this interaction in viral entry remains to be determined.

gH and gL appear to form a tight complex, and in HSV, neither protein is stable without the other. In contrast to gB, the structural studies of gH/gL showed no homology with fusion domains of other viral glycoproteins.¹⁹⁸ Both gB and gH/gL bind, independently of the other, to the profusion domain of gD,^{44,371} and one function of gD may well be to enable formation of complexes with gB and gH/gL assembled in the correct configuration. This interaction does require initiation of fusion.⁴⁰ The exact role of gH/gL has not been determined; however, one hypothesis is that the interaction of gD with its receptors changes the conformation of gH/gL, which in turn induces gB to adopt its fusion active conformation and thus to carry out fusion of the membrane bilayers. The caveat is that any structure of gD interacting with any of the receptors listed previously must be able to activate gH/gL.

Entry and Signaling

Viral entry into Vero cells by fusion at the cell surface leads to increases in intracellular calcium concentration, and blocking this response inhibits viral entry.¹⁹⁰ Binding of virus did not activate calcium release; however, entry triggered local calcium release followed by a more global release of calcium in the cell.¹⁹¹ Binding to heparan sulfate proteoglycans and engagement of a gD receptor was required for the calcium signaling.¹⁹¹ Therefore, calcium seems to play a critical role in HSV entry, although the exact mechanism during entry has not been defined. Infection with ultraviolet (UV)-inactivated virus and binding of gD to HVEM also lead to activation of NF- κ B,^{737,1020} and this could be another signaling pathway activated by infectious virus during productive infection.

Translocation of Capsids to the Nucleus From the Site of De-Envelopment

Upon release from the envelope, capsids are transported to the nuclear pores. Evidence obtained from several labs indicates that the capsids are transported from the site of de-envelopment to the nuclear pore along the microtubular network^{592,1069,1154} by the microtubule motor dynein.¹⁰⁶⁹ Capsids covered with inner tegument proteins recruit microtubule motors and move along microtubules *in vitro*.^{912,1272}

The accumulation of empty capsids at the nuclear membrane was reported by Morgan et al.⁷⁶⁶ and Miyamoto and Morgan,⁷⁵⁸ suggesting that the release of DNA takes place through some port in capsids and does not require its dissolution. Evidence that viral DNA is released at nuclear pores emerged from studies of the HSV-1 Δ B7 mutant. At the nonpermissive

temperature, cells infected with the mutant virus accumulate capsids containing DNA at nuclear membranes. The DNA is released from the capsids on temperature shift-down, and viral gene expression ensues. The *tsB7* mutation maps in the *UL36* gene encoding a tegument protein (VP1-2) that is tightly bound to capsids.^{72,559} More recent studies have shown that the *UL36* protein must be cleaved to allow release of the viral DNA.⁵¹⁸ Host nuclear factor importin β as well as the nuclear pore complex proteins Nup358/RanBP2 and Nup214/CAN are involved in docking of capsids to nuclear pores.^{227,828,849} Furthermore, *in vitro* reconstruction studies showed that capsids bind to nuclear pores and release viral DNA in the presence of cytosol and an energy source. Purified importin β can substitute for cytosol.⁸²⁸ Antibody to importin β blocked the release. The capsid proteins interacting with importin β have not been identified; however, *UL25* has been shown to be involved in uncoating.^{849,897} After docking, viral DNA genomes are likely released through the *UL6* portal, by a pressure-driven ejection mechanism, similar to bacteriophages, in a polarized process with the S terminus first.⁷⁹⁷ It is not known whether histones, the host factor transportin,⁶⁰⁹ or other host or viral factors are then required for targeting of the input genome into the nucleoplasm or the nuclear lamina. A recent study showed that ectopic expression of *UL25*, an inner tegument protein associated with *UL36*, did not block uncoating of the viral DNA but did block viral gene expression⁹⁴⁶; therefore, *UL25* could play a role in movement of the viral genome from the nuclear pore to sites of transcription.

As emphasized elsewhere in this chapter, tegument proteins are released into the cytoplasm concurrently with the capsid. Their destination within the cells varies. As noted earlier, the products of *UL36*, VP1-2, migrate with the capsid to the nuclear pore. The product of *UL41* localizes in the cytoplasm,¹¹¹⁹ whereas VP16, the product of *UL48*, makes its way into the nucleus independently of the capsid.^{73,892}

Viral Gene Expression

Classification of Viral Gene Products: General Summary

The total coding capacity of HSV includes at least 84 transcripts that encode a diversity of proteins, several long noncoding RNAs, and as many as 16 to 17 microRNAs as described previously. In addition, the virions contain and bring into the infected cells a diverse set of mRNAs that do not fully reflect the concentration or composition of the mRNAs present in the infected cells during the assembly of the virions. Viral gene products form several groups expressed coordinately in a cascade fashion^{463,464} (Fig. 60.6). The α (immediate-early) genes are expressed first, followed by β_1 (early-early), β_2 (late-early), γ_1 (leaky-late), and γ_2 (true late). α genes do not require prior viral protein synthesis or their expression. A common property of the six α genes encoding the proteins ICP4, ICP0, ICP22, ICP27, *US1.5*, and ICP47 is the presence of a response element in their upstream sequences. β_1 and β_2 genes exemplified by the *UL29* gene encoding ICP8 and the *UL23* gene encoding the viral TK require for their synthesis at least two of the six α proteins, ICP4 and ICP0. The designations reflect the order of their accumulation in infected cells, although their accumulation is not affected by the absence of viral DNA synthesis. The accumulation of the products of γ_2 genes, as exemplified by

FIGURE 60.6. Schematic representation of the regulation of herpes simplex virus gene expression. Open and filled arrows represent events in the reproductive cycle that turn gene expression “on” and “off,” respectively. **1:** Turning on of α gene transcription by VP16, a γ protein packaged in the virion. **2:** Autoregulation of α gene expression. **3:** Turning on of β gene transcription. **4:** Turning on of γ gene transcription by α and β gene products through transactivation of γ genes, release of γ genes from repression, and replication of viral DNA. Note that γ genes differ with respect to the stringency of the requirement for DNA synthesis. The heterogeneity is shown as a continuum in which inhibitors of viral DNA synthesis are shown to have minimal effect on γ_1 gene expression but totally preclude the expression of γ_2 genes. **5:** Turn off of α and β gene expression by the products of the γ genes late in infection.

the *US11*, *UL38*, and *UL44* gene products, require viral DNA synthesis and the viral proteins ICP4, ICP0, ICP22, ICP27, and *US1.5*. A characteristic of at least some γ_2 genes is that the requirement for viral DNA synthesis is encoded within the 5′ transcribed noncoding domains.

In contrast to the β gene products, the accumulation of γ_1 gene products exemplified by VP5, the major capsid protein, and so forth is affected to various degrees by inhibitors of viral DNA synthesis. Neither β nor γ_1 promoters share common response elements, and most likely, the order and quantity of the gene product that accumulates in the infected cells reflects the embedded cellular response elements and the abundance of transcriptional factors present in the infected cells.

In permissive infected cells, progeny virus accumulates at an exponential rate between 6 and 18 hours after infection and at a reduced, linear rate for at least 24 more hours. In cells exposed to 10 plaque-forming units (PFU) of virus per cell, α gene products reach peak rates of synthesis between 2 and 4 hours after infection, although the actual synthesis of the proteins continues for many hours. The β_1 gene products are expressed very soon thereafter. Overall, β gene products are readily detected by 4 hours after infection but reach highest rates of accumulation between 6 and 12 hours after infection. Viral DNA synthesis can be detected as early as 3 hours after infection and continues for at least 10 to 12 more hours.

State of the Viral DNA and Proteins Prior to the Initiation of Transcription of Viral DNA

CIRCULARIZATION OF VIRAL DNA

Upon entry into the nucleus, viral DNA circularizes quickly at very early times after infection and in the absence of viral

protein synthesis, as first shown using assays that detected (a) viral DNA end joining in cells infected with recombinant viruses lacking internal repeated sequences⁸⁷⁸ or (b) viral DNA that remained in the well in pulsed-field gels.³⁵⁹ These results also led to the development of viral DNA replication models involving theta molecule intermediates and rolling circle mechanisms,¹⁰⁶ as described later. Furthermore, a later study of an HSV recombinant strain containing an insertion of the cleavage-packaging sequence within the genome confirmed the circularization of the HSV-1 genome during productive infection.¹¹⁰³ This study also showed that the end joining reported earlier⁸⁷⁸ was not attributable to concatemer formation or recombination between terminal repeats but rather to circularization.¹¹⁰³ Circularization of viral DNA, formation of endless genomes, and efficient viral replication require the cellular DNA ligase IV/XRCC4, as shown by studies of mutant cell lines and small interfering RNA (siRNA)-mediated knockdown.⁷⁸⁰

ASSOCIATION OF VIRAL DNA WITH HISTONES

Two lines of evidence support the conclusion that the host attempts to silence viral DNA immediately upon entry into the cells.⁵⁶⁰

The first centers on the evidence that the host cell attempts to assemble free incoming DNA molecules into chromatin.¹⁷¹ Following assembly of the incoming DNA with nucleosomes, posttranslational modifications of the histone tails lead to compaction of the chromatin into a form called *heterochromatin*. Reversal of the heterochromatin marks and addition of other histone modifications are needed to form the more open, active chromatin known as *euchromatin*. Similar to transfected DNA, HSV gene promoters introduced on the infecting viral genome are quickly associated with chromatin lacking euchromatin marks at early times postinfection.^{207,824} At later times, the amount of chromatin associated with viral promoters is reduced, and euchromatin marks are associated with the histones associated with the viral genome (H3).^{444,541} Furthermore, nuclease digestion studies have shown that there are few nucleosomes on HSV DNA during productive infection⁶³³ or that they are not arranged in a regular repeating pattern.^{541,635} Other studies have reported that the nucleosomes associated with HSV DNA are less tightly associated than host chromatin.⁶⁰⁸

Although chromatin immunoprecipitation (ChIP) results assume that the fraction of DNA in the immunoprecipitates is representative of the total and should be interpreted with caution, the ChIP studies are supported by other biochemical and genetic results. Thus, a key second support of the hypothesis that the host attempts to silence viral DNA is based on analyses of the requirements for initiation of transcription, which show that the virus mobilizes both host and viral factors to alter the structure of histones and remove the repressors bound to viral DNA as described later and summarized elsewhere.^{560a}

INTRANUCLEAR TARGETING OF HERPES SIMPLEX VIRUS DNA

The input viral genomic DNA is targeted to a location near the nuclear lamina early after entry into the nucleus. Because HSV DNA cannot be detected by *in situ* hybridization until DNA replication occurs, input viral genomes must be detected indirectly. Several lines of evidence argue for the localization of input genomes to the nuclear periphery. First, ICP4 foci were observed at the periphery of the nucleus within minutes of infection.³²⁴ Second, fluorescently tagged repressors to detect

viral genomes with an operator sequence showed genome foci at the nuclear periphery.¹⁰⁷⁶ Third, in cells infected with a virus expressing GFP-VP16 in the presence of an inhibitor of protein synthesis, GFP-VP16 targets to foci at the nuclear lamina.¹⁰⁴⁷ Fourth, early replication compartments, as detected by ICP8 immunofluorescence,^{255,1046} are located near the inner nuclear membrane. Fifth, knockout of the lamin A/C gene in mouse embryonic fibroblasts (MEFs) causes the release of replication compartments from the nuclear periphery.¹⁰⁴⁶ Assembly of the VP16 activator complex likely occurs on the nuclear lamina,¹⁰⁴⁷ possibly because Oct-1 is believed to be associated with nuclear lamins.⁷⁰²

ASSOCIATION OF VIRAL DNA WITH NUCLEAR DOMAIN 10 STRUCTURES

Concurrent with the association of viral DNA with histones, histone and chromatin-modifying enzymes, and repressors, nuclear domain 10 (ND10) or PML bodies are organized adjacent to the newly entered DNA.^{322,489} ND10 bodies have been associated with many functions, including transcriptional activation and epigenetic regulation of gene expression.¹¹⁵⁵ They are dynamic structures regulated by PML. They may contain upward of 20 proteins. They increase in number in cells transfected with DNA upon infection, treatment with IFN, or incubation with histone deacetylase (HDAC) inhibitors. The precise function of ND10 bodies vis-a-vis infection is unknown and remains a controversial issue. Thus, Chee et al¹⁸¹ reported that wild-type virus replicated equally well in murine PML^{-/-} and sibling PML^{+/+} cells. The key finding is that IFN- α or - γ had a major effect in PML^{+/+} cells and minimal effect in PML^{-/-} cells. In contrast, Everett et al³²³ reported that the yields were lower in PML^{-/-} cells than in PML^{+/+} cells. In fact, Chee et al¹⁸¹ observed that replication of an ICP0 mutant virus was threefold higher in PML^{-/-} as compared with PML^{+/+} cells, whereas Everett et al³²³ found that the plaquing efficiency of an ICP0 mutant virus was increased by three- to fivefold by short hairpin RNA (shRNA) knockdown of PML. Therefore, there appears to be agreement that there is a slight increase in ICP0 mutant viral replication when PML is not present in cells during the initial infection of cells but that a larger effect is exerted via IFN- α/β in surrounding cells.

Regardless of their effect on viral replication, two facets of the ND10 functions have become prominent. Foremost, they are the centers of sumoylation that affects the longevity and function of key components of the cell transcriptional apparatus. Second, the dissolution of the ND10 bodies presages the rise of the replication compartments (see Fig. 60.4). Replication compartments form near ND10 bodies, although PML protein and ND10 bodies are not required for their formation.

REQUIREMENTS FOR THE SYNTHESIS AND CHARACTERISTICS OF VIRAL GENE PRODUCTS

Transcription of viral DNA takes place in the nucleus, and as would be expected, all viral proteins are synthesized in the cytoplasm. The key constituent of the viral transcriptional apparatus is host RNA polymerase II,^{16,236} and several viral proteins either become components of the transcriptional apparatus or recruit specific cellular proteins, as discussed in detail later. RNA pol II is responsible for transcription of all viral genes during infection, although viral gene products may modify its activity and structure.

Productive infection

The studies reported largely during the past 5 to 10 years have altered our perception of viral gene expression from serial activation of transcription to serial derepression and transcriptional activation of the viral genome. It is convenient to describe the key events in viral gene expression in terms of three checkpoints (Fig. 60.7). The first involves the specific derepression of α gene promoters and activation of transcription of α genes. In brief, the tegument protein VP16 serves both of these functions by becoming part of a tripartite complex comprised of octamer-binding protein 1 (Oct-1), which binds to the α promoter response element described below, and host cell factor 1 (HCF-1). The complex performs two functions. First, it recruits lysine-specific demethylase 1 (LSD1) to demethylate H3K9me2 and at least one HAT—CLOCK—and most likely other factors to derepress α promoters. Second, it recruits transcriptional factors to initiate the expression of α genes.

The expression of β and γ_1 genes, the second checkpoint, requires ICP4 and, at low multiplicities of infection, ICP0. A major role of ICP0 is the inactivation of the HDAC1 or 2/CoREST/LSD1/REST repressor complex. The CoREST/LSD1/REST complex is best known for its role in repressing genes in nonneural cells. The complex through REST binds RE1, a large and somewhat degenerate response element present at more than 5,000 sites in the human genome. ICP0 also enhances the recruitment of several other factors (e.g., cyclin D3, CDK4, BMAL1, and CLOCK) to the nuclear domain that ultimately becomes the viral replication compartment. ICP4 is a component of the transcriptional complex involved in the expression of all post- α genes. The role of ICP4 is in promoting the initiation of transcription of the post- α genes.

As noted earlier, the expression of γ_2 genes, the third checkpoint, requires ongoing DNA synthesis, ICP4, and ICP0. Except for the apparent involvement of response elements in the 5' transcribed noncoding domain and the important roles of ICP27 and ICP22, little is known of the mechanisms underlying expression of γ_2 genes.

DEREPRESSION AND TRANSCRIPTION OF α GENES

The key players in the derepression and transcriptional activation of α genes are the protein complex involving the viral VP16 protein; the unique α gene response element; the host factors recruited by the VP16 complex, including Set1, LSD1, and CLOCK; and a large number of transcriptional factors, discussed later.

VP16 encoded by U_L48 is one of 18 virion tegument proteins. In productively infected cells, it forms complexes with VHS encoded by U_L41 and VP22 encoded by U_L49 . It is also an essential structural component of the virion. Upon entry into the host cell in the virion, it is a key component of complex of proteins that derepresses and activates α gene expression. Upon

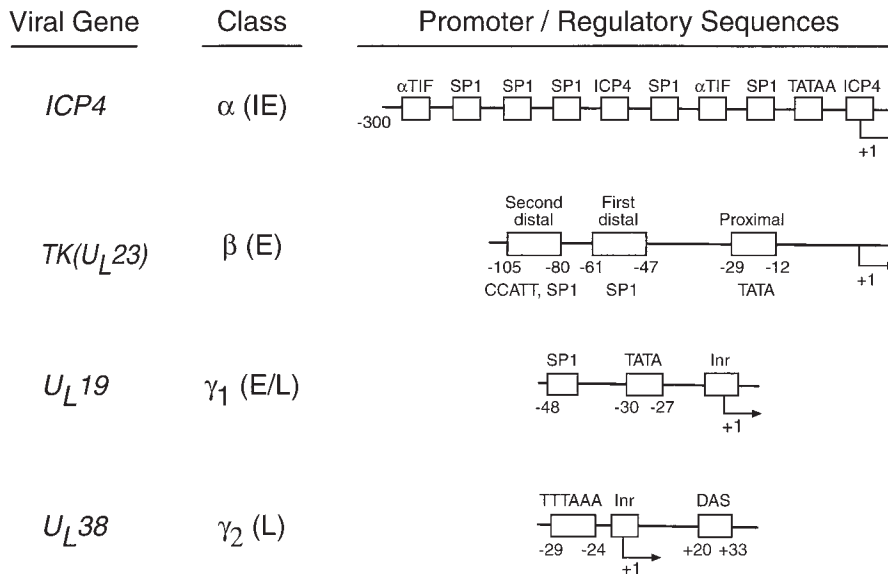

FIGURE 60.8. Diagram of the structure of prototypic herpes simplex virus gene promoters. The promoter/regulatory sequences of prototypic genes of α , β , γ_1 , and γ_2 kinetic classes are diagrammed.

A key step in the expression of α genes is the recruitment of LSD1 to the viral α gene promoters by the VP16/HCF-1/Oct-1 complex. LSD1 demethylates H3K9me2 bound to α promoters to enable α gene transcription.⁶⁴⁵ Depletion of LSD1 or pharmacologic inhibition of LSD1 increased H3K9me3 modification of histones associated with HSV α gene promoters and decreased α gene transcription.⁶⁴⁵ It is noteworthy that LSD1 is normally stable in association with CoREST and is rapidly degraded in the absence of its partner. Indeed, depletion of CoREST or REST prior to infection results in the depletion of LSD1 and a decreased accumulation of α gene products.²⁹⁴ Because the CoREST/REST complex is not associated with the α gene promoters, it may be inferred that LSD1 is detached from the CoREST/REST complex by the HCF-1–VP16 complex or that HCF-1 in the VP16 complex recruits LSD1 that is not associated with CoREST/REST.⁶⁴⁵ Furthermore, HCF-1 is part of the Set1 and MLL1 histone H3 Lys4 methyltransferase complexes; therefore, the transactivation complex recruits the HCF-1–Set1 or HCF-1–MLL1 histone methyltransferase (HMT) complex to α promoters resulting in the euchromatic histone modification; trimethylation of the histone H3 lysine

The cellular hSNF2H chromatin remodeling complex subunit has also been linked to efficient ICP0 gene expression.¹²⁹

This host factor is associated with the *ICP0* gene promoter at early times postinfection¹²⁹ but has not been linked to VP16.

SHUT OFF OF α GENE EXPRESSION OR FUNCTION

There is significant evidence that HSV controls the accumulation or function of at least two α proteins: ICP4 and ICP0.

1. ICP4 can repress its own expression. ICP4 binds to two sets of DNA sequences. The first, reported by Faber and Wilcox,³²⁵ was ATCGTCNNNNYCGRC and is defined as the consensus binding site. The second set of sequences bears no relationship to the consensus binding sites or, for that matter, to each other.⁷⁴⁹ Consensus binding sites that span transcription initiation sites serve as sites for repression of transcription by ICP4, as illustrated by the *ICP4* gene in Figure 60.8. Another consensus binding site spans the transcription initiation site of *ORF P/ORF O*. The effectiveness of the binding site in repressing transcription in the context of the viral genome varies depending on the distance from the transcriptional initiation site. The farther downstream it is, the less the repression. Also, displacement by half of a helical turn is more effective in minimizing repression than a full helical turn.⁶³⁸ It should be noted that whereas mutagenesis of the ICP4 binding site across the transcription initiation site resulted in a tenfold increase in accumulation of transcripts, the added mutagenesis of the upstream and more distant binding site had barely a twofold effect on transcript accumulation.⁶³⁸

It is less clear whether ICP4 represses the expression of the other α genes. ICP4 binds upstream of the *ICP0* gene transcriptional initiation site,⁵⁹⁵ and ICP4 represses the *ICP0* promoter in transfected cells.³⁶⁵ Nevertheless, the specific effect of ICP4 on *ICP0* gene expression in infected cells has not been defined by construction of a mutant virus with the binding site in the *ICP0* gene mutated. Consensus ICP4 binding sites are not evident in or near the promoters of the other α genes.

2. As noted previously, ICP4 blocks the expression of ORF O/ORF P by binding to the consensus binding site or at the transcription initiation site of these genes. Studies of the function of these genes revealed that the ORF O protein blocks the binding of ICP4 to its consensus binding sites.⁹¹⁶ The precise role of ORF O remains to be defined.
3. During productive infection, β gene products down-regulate α gene expression.⁴⁶³ One β protein identified as a candidate is ICP8, the single-stranded DNA binding protein encoded by the *UL29* gene. ICP8 decreases the expression of all genes from the parental viral DNA molecules^{381,382}—in particular, transcription of the gene encoding ICP4.³⁸³ The mechanism of this effect of ICP8 is not known but may involve the sequestration of viral DNA molecules in replication complexes, changes in the conformation of viral DNA, or displacement of DNA to sites of DNA synthesis away from those required for transcription.
4. During the first 6 hours after infection, ICP0 is localized in the nucleus. Thereafter, it accumulates in the cytoplasm. The half-life of ICP0 at very early times during the nuclear phase is less than 1 hour but increases with time after infection. Analyses of the cleavage products suggest that ICP0 is degraded by at least two different proteases.⁴⁰¹ Therefore, ICP0 nuclear function is limited by its transport to

the cytoplasm and/or rapid turnover in the nucleus as the infection progresses.

5. At early times, VHS has been shown to degrade both viral and cellular mRNAs. Observation of cells infected with *vhs* mutants that the transition from α to β and subsequently to γ protein synthesis lags behind that observed in wild-type virus-infected cells led to the conclusion that one function of *vhs* is to synchronize sequential viral gene expression.⁶⁰⁵ The proposed model is that the rate of transcription of viral genes exceeds the ability of VHS to degrade the mRNAs, and that unless destabilized, α mRNAs would outcompete β mRNAs, and so on.

EXPRESSION OF β AND γ_1 GENES

Because the temporal order of expression of β and γ_1 genes overlap, it is convenient to lump them together. Expression of these genes requires ICP4 and is increased by ICP0, in particular at low multiplicities of infection. Expression of these genes requires, to a variable extent, also ICP27, ICP22, and *UL5*, and, in the case of γ_1 genes, the onset of viral DNA synthesis. It is convenient to consider the contribution of each gene product separately.

ICP0

ICP0 is a multifunctional protein that plays the major role in the derepression of the post- α genes by countering host chromatin silencing mechanisms. ICP0 is not essential for viral replication in cell culture at high multiplicity of infection (MOI) or in experimental animal systems but does increase viral replication in animals and at low MOI infection of cultured cells.⁴⁰⁹ At low MOI, cells infected with *ICP0* deletion mutants yield approximately 10- to 1,000-fold less virus than cells infected with wild-type virus in certain cell types. At more than 5 PFU per cell, the yields of Δ ICP0 mutant virus may be similar to those of wild-type virus. The cell line most permissive for Δ ICP0 mutant viruses is U2OS. Thus, U2OS cells serve as the standard for infectivity titrations of ICP0 mutant virus stocks for experimental studies. Even using this cell line for titrations, the particle:PFU ratio for ICP0 mutants may be higher than the wild-type or rescued viruses; thus, this may be a factor in certain experiments. During the first 6 hours after infection, ICP0 accumulates in nuclei, initially near ND10 structures^{681,721}; later, it expands to occupy most of the nucleus. In wild-type virus-infected cells, ICP0 then accumulates in the cytoplasm between 6 and 9 hours after infection. ICP0 turns over very rapidly at early times (half-life <1 hour) and at much slower rates late in infection.

The major phenotypic properties of ICP0 are threefold. Foremost, ICP0 promotes but is not essential for viral replication in experimental animal systems⁶³² and in cell culture at very low MOI. In these cells, Δ ICP0 mutants express α gene products; however, the transition to β and γ gene expression does not ensue. A second key phenotypic property of ICP0 is that it acts as an indiscriminate promiscuous transactivator of both viral and nonviral genes introduced into cells by transfection or infection. Lastly, ICP0 plays very prominent roles in viral defenses against cellular innate immune responses. It is convenient to look at the molecular mechanisms underlying each of the phenotypic properties separately.

Several observations led to our current models by which ICP0 is believed to enable the expression of β genes by countering the epigenetic silencing of these genes. First, HDAC inhibitors

such as trichostatin A⁴⁵³ and sodium butyrate⁸⁸⁴ could rescue at least part of an ICP0 mutant defect. This argued that one of the functions of ICP0 was to inhibit HDAC activity. Second, ICP0 was reported to interact with class II HDACs and to reverse repressive effects of these HDACs in transfected cells.⁶⁷² Third, ICP0 binds to CoREST *in vitro* and dislodges HDAC1 from the HDAC1/CoREST/LSD1/REST (HCLR) complex in wild-type virus-infected cells. Over time, a fraction of CoREST, HDAC1, and LSD1 are exported from the nucleus to the cytoplasm of wild-type virus-infected cells but not from Δ ICP0 virus-infected cells. This step requires the onset of viral DNA synthesis and may involve other viral gene products.⁴⁰⁰ Fourth, replacement of both copies of the *ICP0* gene with a gene encoding a dominant negative CoREST capable of binding REST but unable to bind HDAC1 led to a 100-fold increase in the yield of virus in Vero cells and at least a 10-fold increase in HEP-2 cells following low PFU/cell infection.⁴⁰² The involvement of HDACs was reinforced by the observation that HDAC1 and 2 are phosphorylated by U₅3 protein kinase and that expression of reporter genes is augmented by co-transfection with U₅3.⁸⁸³ Lastly, a virus encoding an ICP0 unable to bind CoREST showed reduced ability to reactivate quiescent HSV-1, consistent with a role for REST/CoREST/HDAC1/2/LSD1 in repression of quiescent genomes.³³² Despite the weight of this evidence, knockdown of CoREST did not affect replication of an *ICP0* mutant in human HepaRG cells, terminally differentiated human hepatic cells.³¹⁸ The differences here may be owing to the differences in cell types used or to the fact that CoREST both inhibits viral gene expression and stabilizes LSD1, which is needed for viral α gene expression.¹³¹⁷

The hypothesis that ICP0 counters silencing by reversing host chromatin silencing mechanisms is confirmed by the observation that ICP0 promotes decreased total histone H3 association with viral promoters and increases the acetylation of histone H3 that is associated with viral promoters, a histone modification associated with euchromatin or active chromatin.²⁰⁷ Furthermore, ICP0 promoted the removal of heterochromatin markers from viral chromatin during reactivation from quiescent infection in cell culture.³³² An unresolved issue is whether ICP0 also affects host chromatin. ICP0 increases the expression of host gene products, including p21, gadd45, and mdm2, potentially owing to chromatin effects.⁴⁵³ HSV infection reduces histone H3 levels on the *GAPDH* gene promoter⁴¹⁸ but not on a *GAPDH* pseudogene.²⁰⁷ Further studies are warranted to determine the effects of HSV infection and ICP0 specifically on host gene chromatin.

ICP0 has at least three other functions that contribute to the transactivation of viral genes. The first two relate to the binding of ICP0 to BMAL1 and cyclin D3.⁵³⁷ BMAL1 is a partner and stabilizer of the CLOCK HAT. First, recent studies have shown that CLOCK and its partner BMAL1 localize at ND10 structures and the replication compartments¹¹⁷⁴ that evolve near them. BMAL1 binds to ICP0, and the data suggest that ICP0 enhances the recruitment of CLOCK and stabilizes it. Overexpression of functional CLOCK enhances the replication of Δ ICP0 mutants, whereas overexpression of CLOCK lacking HAT activity did not. Depletion of CLOCK drastically reduced expression of α genes. It is noteworthy that cells depleted of CLOCK produced only small amounts of ICP0 but no other α proteins.⁵²⁶ These results reinforced the hypothesis generated in other studies in cells infected at low multiplicities that ICP0

is made first, that ICP0 helps recruit other factors, and that other α proteins and more ICP0 are then produced. A corollary of this hypothesis is that the CLOCK HAT is essential for the expression of the full complement of α proteins but not for the initial transcription of the gene encoding ICP0. CLOCK is a component of the transcriptional complex throughout viral replication.⁵³⁰

Second, the interaction of cyclin D3 with ICP0 is abolished by the D199A substitution. The mutated ICP0 is also retained in the nucleus throughout the infection. The Δ ICP0 mutants were complemented by replacement of ICP0 with cyclin D3; thus, a key function of ICP0 appears to be the recruitment of cyclin D3 to replication compartments to activate cdk4.⁵²⁷

Third, the interaction of ICP0 with ND10 and, in particular, the degradation of PML and of other components of ND10 play a role in the activation of expression of β genes; however, the mechanism of degradation of PML is more difficult to define in molecular terms. The fundamental conclusion reported elsewhere is that the degradation of ND10 and its components and transition from α to β gene expression are interdependent.

The functions of ICP0 as a promiscuous transactivator were recently re-examined in detail. In brief, transfection of cells with DNA containing expressible reporter genes, and lacking known promoter or ORFs, results in an increase in the size and number of ND10 structures. Infection of cells transfected with extraneous DNA results in retention of ICP0 in the nucleus that depends on the size and amount of DNA but not on the content or composition of the DNA. The hypothesis that ICP0 is retained in the nucleus until all DNA at ND10 bodies is “processed” is supported by the concurrent expression of reporter gene and viral genes in cells infected with wild-type virus but not in cells infected with Δ ICP0 mutant virus.⁵²⁹ This finding suggests that the tasks of degrading ND10 and its components and the derepression of viral genes occur concurrently until both are completed.

The domains on ICP0 (Fig. 60.9) that are relevant to gene activation include the RING domain in exon 2, which is a C₃HC₄ zinc binding domain⁶⁸ from residues 106 through 149 containing a ubiquitin E3 ligase activity,^{116,410,1184} the CoREST binding site from residues 669 through 718,⁴⁰² and the BMAL1 binding site from residues 20 through 241.⁵³⁷ Two studies have shown that the RING domain and CoREST binding site are functionally related, in that both are involved in IFN sensitivity⁴⁰⁴ and viral gene activation.^{331,404}

FUNCTION OF THE RING DOMAIN LIGASE ACTIVITY

The RING domain E3 ligase activity is essential for ICP0's functions in transactivation of post- α gene expression and for promotion of viral replication at low MOI. However, the molecular mechanism of these effects has not been elucidated. ICP0 has been linked to the degradation of numerous proteins in that ICP0 mutant viruses do not show the normal degradation associated with HSV infection. However, there is little evidence that ICP0 directly ubiquitinates several of these proteins. ICP0 has been linked to degradation of PML^{183,321}; the SUMO-modified form of Sp100^{183,772,846}; centromere proteins CENP-A, -B, and -C^{320,670,671}; the catalytic subunit of DNA-protein kinase^{629,847}; the ubiquitin-specific protease 7 (USP7)¹¹⁵; the RNF8 cellular RING finger ubiquitin ligase⁶⁴⁹; ubiquitinated histones⁶⁴⁹; and the RNF168 cellular E3 ligase.⁶⁴⁹ However,

FIGURE 60.9. Diagram of the domain structure of ICP0. Shown are functional domains and protein-binding sites. Green bar at left indicates the BMAL1 binding region.

ICP0 has been shown to interact directly with only a few of these proteins, such as USP7.¹¹⁵ Therefore, it remains a paradox how ICP0 promotes the degradation of the large number of proteins. ICP0 binds to USP7 and promotes its ubiquitination *in vitro*.¹¹⁵ ICP0 binds to the DNA repair protein RNF8, and purified ICP0 ubiquitinates RNF8 *in vitro*.⁶⁴⁹ These are the only known direct substrates of the ICP0 E3 ligase activity. The correlation of ICP0 with degradation of PML and Sp100 and disruption of ND10 bodies raises this as a potential important activity of ICP0; however, there is no evidence of direct interaction of ICP0 with these proteins. The only direct evidence that ICP0 degrades PML and SP100 is the fact that dominant negative UbCh5A blocks the degradation.⁴⁰³ The question of the precise molecular interactions that lead to the effects of ICP0 is likely to be an important one for the field.

ICP4

ICP4 fulfills the second function needed for post- α gene transcription: recruitment of RNA polymerase II to these gene promoters. ICP4 is required for maximal levels of all post- α gene expression,^{204,561,894,1223} and the effect of ICP4 is exerted at the transcriptional level in infected cells, as demonstrated by nuclear run-off assays.³⁸³ ICP4 has been shown to also activate gene expression in transfected cell assays^{319,366,827,910} and in *in vitro* transcription systems.³⁹⁹

Two properties of ICP4 are relevant to its roles in regulation of viral gene expression: its ability to bind to DNA and its ability to interact with transcription factors. ICP4 has both sequence-specific and nonspecific DNA-binding activities.^{595,750} Binding of ICP4 to specific DNA sites seems unlikely to explain

its transactivation activity, because the strongest affinity of ICP4 is for sites known to repress rather than activate transcription (e.g., at the transcription initiation sites of the *ICP4* or *ORF P* genes), and destruction of the sole sequence-specific binding site of ICP4 upstream of the transcription initiation site of the *ICP4* gene attenuated repression in the context of the viral genome.⁶³⁸ With regard to the role of DNA binding in the transactivation function of ICP4, early mutational analysis showed that the sequence-specific binding activity of ICP4 correlated extensively with its ability to activate β gene expression in infected cells.¹⁰³³ In addition, insertion of ICP4 binding sites was reported to render reporter genes responsive to ICP4, albeit in transfected cells.¹¹³³ However, one viral mutant has been obtained in which the DNA-binding activity of ICP4 was greatly reduced but the ability to activate β genes in infected cells was nearly unchanged.¹⁰³² Furthermore, most post- α genes do not have recognizable consensus binding sites for ICP4, and mutation of consensus sites has not affected the level of expression of the surrounding genes in the viral genome.¹⁰⁶⁰ Thus, the bulk of the data from studies of infected cells has failed to correlate ICP4 DNA binding with transactivation of β genes. Nevertheless, there may be a role for the DNA-binding ability of ICP4 in stabilizing the binding of cellular transcription factors to β and γ gene promoters.^{841,842}

Second, ICP4 has been shown to interact with basal transcription factors to form complexes with TBP, TFII-B, and TAF250^{158,641,991,1061} as well as ICP27, ICP22, and the cellular CLOCK HAT.⁵³⁰ ICP4 promotes the formation of transcription preinitiation complexes *in vitro* on the *gC* gene promoter, at least in part by stimulating the binding of TFIID to the promoter to form preinitiation complexes.³⁹⁴ ICP4 also interacts with the mediator complex⁶⁴¹—a large protein complex that bridges upstream activators and the preinitiation complex. Thus, most current models for ICP4 transactivation of viral β and γ genes involve interactions with cellular transcription factors to stimulate transcription. It is still not clear how this stimulation is focused specifically on viral genes. Again, given the ability of ICP4 to both activate and repress gene expression, it is important to distinguish in which cases the binding of cellular transcriptional factors represents the transactivation or the repressive function of ICP4.

ICP27

ICP27 is an α protein that is reported to have multiple regulatory functions, including promoting expression of certain β proteins, late gene transcription, RNA export from the nucleus to cytoplasm, and translation of viral mRNAs. Early studies of viral gene expression concluded that ICP27 is required only for viral DNA replication and late gene expression^{936,980}; however, further studies showed that ICP27 is also needed for efficient expression of certain β genes^{729,990,1175}—in particular, the less abundant viral DNA replication proteins.¹¹⁷⁵ Thus, ICP27 is required at least in part indirectly for viral DNA replication by increasing the mRNA levels of β gene products essential for viral DNA synthesis. These studies have shown that ICP27 increases the mRNA levels for these β genes, although it has not been determined if this effect is transcriptional or posttranscriptional. ICP27 affects the cytoplasmic levels of only a subset of β mRNAs because northern blot studies have shown that an ICP27 null mutant virus expresses levels of ICP8 mRNA at 6 hours postinfection (hpi) that are equivalent to wild-type virus.¹¹⁷⁵

HSV ICP27 mutant viruses are defective for late *gC* gene transcription, as assayed by intracellular pulse labeling.⁴⁹⁷ Consistent with this, ICP27 associates with RNA polymerase II holoenzyme¹³¹⁴ through its interaction with the C-terminal domain of the large Pol II subunit,²⁴⁵ consistent with an ability to enhance initiation or termination of transcription. ICP27 is also associated with the CLOCK HAT.⁵³⁰ ICP27 has been shown to bind to ICP4,⁸³⁸ to alter the phosphorylation of ICP4,^{936,1107,1276} and to localize to replication compartments.²⁵⁷ ICP27 interacts directly with ICP8,⁸²⁹ which associates with viral progeny DNA.⁶²⁷ Therefore, ICP27, through its interactions with ICP8 and RNA pol II, is proposed to link pol II to progeny viral DNA to promote late viral gene transcription.⁸²⁹ Consistent with this, immunofluorescence studies have shown that certain ICP27 mutant viruses are defective for recruitment of pol II to replication compartments in infected cells.²⁴⁵ These properties are all consistent with effects on transcription of late HSV genes. The ability of ICP27 to promote γ viral gene expression is at least partly distinct from its ability to stimulate viral DNA synthesis, because at least one mutant virus, *n504*, separates these two functions. This mutant is defective for γ gene expression, in particular γ_2 proteins, while maintaining normal levels of viral DNA synthesis.⁹³⁷ This mutant virus has further been used to demonstrate that ICP27 stimulates transcription of γ genes independently of its role in stimulating β gene expression and viral DNA replication.⁴⁹⁷ This study found that ICP27 promotes transcription of at least two γ_2 genes, *U_L44* and *U_L47*, in infected cells, as assayed by *in vivo* pulse labeling of RNA, without any apparent effects on transport or stability of these transcripts. ICP27 has also been reported to affect the elongation, termination, and/or polyadenylation site selection during transcription.^{419,729,734}

ICP27 has been shown to shuttle between the nucleus and cytoplasm^{736,874,994,1070} and is reported to promote RNA export in several studies.^{184,994,1070,1071} However, in some cases, the viral mutants used may have an additional defect in late gene transcription.¹⁰⁷⁰ There are differing results on the role of ICP27 in viral mRNA export. One study found that the β ICP8 mRNA is present in the cytoplasm of an ICP27 null mutant virus-infected cell at nearly normal levels (82%) compared to that in wild-type virus-infected cells.¹¹⁷⁵ Another study found substantially lower amounts of ICP8 as well as other E and L mRNAs in the cytoplasm of ICP27 mutant-infected cells.⁹⁹⁴ Furthermore, measurement of viral transcript levels by microarray technology shows that a broad spectrum of viral poly (A)⁺ transcripts are retained in the nucleus in cells infected with ICP27 mutant viruses,⁵¹² whereas studies looking at specific viral mRNAs using northern blot hybridization found that (a) the long *U_L24* gene transcript was increased in the nucleus of ICP27 mutant-infected cells but the short *U_L24* gene transcript was unaffected⁸⁵⁸; (b) VP16 mRNA export was not altered in ICP27 mutant infected cells,³¹³ and (c) ICP27 is not required for cytoplasmic accumulation of *gD* and ICP5 mRNAs.³³⁸ Therefore, there are only a limited number of specific transcripts that show a dependence on ICP27 for nuclear export and cytoplasmic accumulation. In total, ICP27 binds to pol II, promotes late gene transcription, promotes association of RNA-binding proteins to late transcripts, may escort mRNAs to the cytoplasm, and enhances the binding of translation factors to mRNA. Further studies should define how ICP27

participates in all of these processes, from synthesis of the mRNAs to their translation.¹¹¹⁸

β GENES AND THEIR REGULATION

Unlike α genes, β or γ genes do not have unique promoter elements that instantly predict the timing, duration, or abundance of gene expression. Rather, the overall impression is that they appear to be made up of a diversity of elements, and both the organization and the context in which these elements are placed determine the expression of the gene. Nevertheless, the β gene promoters thus far studied contain binding sites for two to three cellular transcription factors upstream of the transcriptional start site (see Fig. 60.8—*tk* gene). The mechanism of activation of β genes has also been approached in studies attempting to map the *cis*-acting sequences needed for activation by virus infection or ICP4. The most extensively studied β gene promoter is that of the *U_L23* or *tk* gene. Extensive mutagenic analyses of the promoter showed that the sequences needed for basal level transcription⁷³³ or activated transcription²¹³ were the same (see Fig. 60.8): a proximal signal from bp -12 to -29 containing a TATA box and two distal signals from bp -47 to -61 and -80 to -105 containing an SP1 transcription factor binding site and an SP1 site and a CCAAT transcription factor (CTF) site, respectively. These studies also supported the hypothesis that ICP4 transactivates β gene promoters through interactions with cellular basal transcription factors.

EXPRESSION OF γ GENES

Once viral DNA replication has initiated, expression of γ genes is increased,⁴⁶⁵ largely as a result of increased transcription.³⁸³ Late transcription takes place in replication compartments within the infected cell nucleus, as evidenced by (a) the localization of ICP4^{562,917} and pol II⁹³⁹ to replication compartments at late times and (b) RNA-pulse labeling of replication compartments at late times.⁸⁷⁵

It is known that transcription of late genes increases upon replication of the viral genome³⁸³; that the alteration in the viral DNA template is *cis*-acting⁷²⁴; and that the ICP4, ICP22, ICP27, and ICP8 proteins are required. The *cis*-acting effect on the template could be owing to changes in the viral DNA molecules themselves by exposure of single-stranded regions or by conversion of the viral genome from a circular form to a linear form. Alternatively, the *cis*-acting effect could be owing to proteins tightly bound to the viral parental DNA that do not exchange to other DNA molecules in the infected cell. ICP4 promotes γ gene transcription by promoting the assembly of preinitiation complexes on the γ_2 *gC* gene promoter.¹³⁰⁵ ICP27 and ICP8 have been hypothesized to stimulate late gene transcription by recruiting pol II onto progeny DNA through a direct interaction that bridges ICP27 bound to Pol II with ICP8 bound to viral progeny DNA.⁸²⁹ Additional interactions of pol II holoenzyme with ICP4 would lead to preinitiation complexes on late gene promoters.

As a general rule, whereas sequences upstream of transcriptional initiation sites are sufficient to endow a reporter gene with the kinetics of β gene expression both in transfected cells and in the context of the viral genome,^{213,1225} this is not generally true of γ genes.^{724,1048} In the context of the viral genome, expression of reporter genes as γ_2 genes also requires regulatory elements present in the 5' transcribed noncoding domains.⁴⁶² Even then, such chimeras are expressed as β genes

in cells transfected with the chimera and then superinfected with the virus.¹⁰⁴⁸

The HSV γ_1 promoters have not been studied as extensively as some of the other viral promoters; however, the *ICP5* (*U_L19*) gene promoter elements have been defined (see Fig. 60.8). The essential elements of the minimal *ICP5* gene promoter are an SP1 binding site at -48, a TATA box at -30, and an essential *cis*-acting element between -2 and +10 whose sequence resembles the HIV initiator element.⁴⁷⁴ A cellular factor that binds at the cap site has been identified.⁴⁷³ The γ_1 gene promoters are heterogeneous in that the minimal *VP16* gene promoter from bp -90 to +6 contains an E box (CACGTG) at -85, a CAAT box at -77, an SP1 site at -48, and a different initiator element.⁶⁴⁶

Analyses of γ_2 viral gene promoters have shown that the upstream sequences consist of a TATA box with few other upstream transcription factor binding sites^{334,461,462,513} and with additional sequences needed for activation within the 5' UTR.^{408,462,724,1095,1226} For example, the γ_2 *U_L38* gene promoter (see Fig. 60.8) contains three elements: (a) an unusual TATA element with the sequence TTAAAA at -31, (b) a consensus initiator element at the transcriptional start site, and (c) a downstream activation sequence (DAS) from bp +20 to +33 that is required for normal levels of gene expression.⁴⁰⁸ The DAS seems to increase transcriptional initiation,⁴⁰⁷ and several other HSV γ genes, including *U_S11*, *gC* (*U_L44*), *gB* (*U_L27*), *L/ST*, and *U_L49.5*, have similar downstream control elements in their promoter.⁴⁰⁷ In addition, the *gC* gene DAS can partially substitute for the *U_L38* DAS,⁴⁰⁷ suggesting that common mechanisms may act on the different DAS sequences. The Ku70 or DNA-binding subunit of the DNA-dependent protein kinase⁸⁷³ and hTAF(II)70⁸⁷² have been identified as factors binding to the DAS. Given that HSV infection leads to the degradation of the catalytic subunit of DNA-protein kinase and loss of kinase activity,⁶²⁹ this effect may free up the Ku70 subunit for interaction with viral DNA.

ROLE OF ICP22/U_S1.5 IN LATE GENE EXPRESSION

ICP22 is required in certain cell types for optimal accumulation of a subset of late (γ_2) proteins exemplified by the *U_S11*, *U_L38*, and *U_L41* proteins.^{823,885,905} This function maps in the C-terminal domain of ICP22 and can be contributed by the smaller *U_S1.5* gene product.⁸²³ Two distinct functions mapping to that site may account for this activity. It is not known whether the effect is transcriptional or posttranscriptional; however, several interactions and effects of ICP22 could explain this function. First, ICP22, in conjunction with the *U_L13* protein kinase, mediates the phosphorylation of RNA polymerase II.^{673,938} ICP22, in conjunction with the *U_L13* protein kinase, mediates the degradation of cyclins A and B and the acquisition of a new partner, the *U_L42* DNA polymerase processivity factor. The cdc2-*U_L42* complex recruits topoisomerase II α in an ICP22-dependent manner to promote γ gene expression.⁸⁻¹⁰ It has been proposed that the ICP22/*U_L42*/topoisomerase complex enables transcription of newly synthesized concatemeric DNA. This DNA accumulates in tangles, which may block access of the transcriptional machinery in the absence of ICP22. Second, ICP22 also causes the loss of serine 2 phosphorylated pol II,³⁴⁸ which could affect activity levels of pol II. Third, ICP22 binds cdk9, and this complex phosphorylates the C-terminus of pol II.³⁰⁵ Finally, ICP22 promotes the formation of nuclear

foci near replication compartments that contain chaperone proteins, proteasomal components⁷¹ that could affect late viral transcription in replication compartments.

EXPORT OF VIRAL RNA FROM THE NUCLEUS

Export of cellular mRNA from the nucleus is coupled to RNA splicing in the nucleus. Because HSV infection inhibits RNA splicing, this raises the question of the mechanism for transport of nascent transcripts from the site of transcription to the cytoplasm. In addition to the potential role of ICP27 in nuclear export of viral RNAs as described previously, there is accumulating evidence that a new export system is assembled in infected cells. Recent studies have shown that HSV replication compartments coalesce at nuclear speckles and that this movement involving active transport using nuclear actin and myosin and ongoing transcription promotes export of late viral mRNAs.¹⁷⁵

TRANSLATION

Like all viruses, HSV must utilize the host protein synthesis apparatus for synthesis of its own proteins. As a result, HSV has evolved several strategies to commandeer the host ribosomes and translation factors for its own protein synthesis. First, HSV infection inhibits host transcription and RNA splicing, thereby interrupting the supply of host mRNA to the cytoplasm, as described elsewhere in this chapter. Furthermore, HSV induces the degradation of many pre-existing host mRNAs through the *vhs* function.⁹²⁵ In addition, HSV blunts the host innate responses such as IFN and protein kinase R (PKR) responses, both of which are described in more detail later. HSV infection has also been shown to exert some specific effects on the host translation apparatus to enhance translation of its mRNA. In addition to decreasing the host mRNA levels, HSV infection stimulates the activity of the cellular cap-dependent translational machinery by increasing the formation of the eIF4F cap-binding complex. This is accomplished by inducing phosphorylation and proteasomal degradation of the eIF4E binding protein 1 (4E-BP1), which releases eIF4E to facilitate eIF4F complex formation.¹²¹⁰ HSV infection also causes phosphorylation of eIF4E, which enhances viral protein synthesis, particularly in quiescent cells.¹²¹⁰ ICP0 is required for both of these effects; however, this is at least in part an indirect effect because ICP0 stimulates the expression of the viral ICP6,²⁶⁸ which binds to the eIF4G protein, a component of the eIF4F complex, and promotes the formation of the complex.¹²⁰⁹ HSV also activates eIF4E via *U_S3* phosphorylation of tuberous sclerosis complex 2 (TSC2), allowing constitutive activation of mTORC1.²⁰⁰

HSV ICP27 has also been shown to interact with host translation factors^{339,622} and to enhance the translation of late mRNAs in infected cells,^{313,338} or an mRNA to which ICP27 is tethered.⁶²² The mechanism of this effect of ICP27 on viral translation has not been elucidated; however, ICP27 has been recently reported to act with *U_L47* to promote the nuclear accumulation of the cellular PABP²⁷⁹; however, others have not observed this effect.⁹⁸⁵

ICP0 has several potential functions during its cytoplasmic sojourn. ICP0 has been also shown to interact with elongation factor 1 δ .⁵³⁶ The interaction of ICP0 with eF-1 δ , an elongation factor responsible for adenosine biphosphate-adenosine triphosphate (ADP-ATP) exchange, appears to be significant inasmuch as a truncated ICP0 polypeptide containing the

binding site interfered with *in vitro* synthesis of a reporter protein. The significance that HSV places on eF-1 δ is underscored by the observation that U_L13 phosphorylates eF-1 δ and that this protein is also phosphorylated in cells infected with representative β - and γ -herpesviruses. ICP0 also forms a complex with CIN85 and Cbl—a ubiquitin ligase that also carries cargo from the cells surface.⁶⁴⁴ Furthermore, ICP0 was shown to bind the SH3 domains of the adaptor protein CIN85 and members of the *src* family.^{642,644} The function of ICP0 as a ubiquitin ligase is firmly established. ICP0 has been reported to interact with at least two additional ubiquitin-conjugating enzymes, UbCH6 and UbCH9; however, the targets of these E2 enzymes have not been firmly established.^{116,410} On the other hand, several proteins turn over rapidly in infected cells, and some have been specifically linked to expression of ICP0. Yet not all the cellular proteins that disappear during productive infection are likely to be the targets of ICP0. For example, the receptor of TNF α turns over very rapidly; in infected cells, it is not replenished because of the degradation of its mRNA.⁶⁴³ A similar case has been made for the disappearance of IFN- γ receptor.⁶⁴² Accelerated degradation of cellular proteins by posttranslational modifications initiated by phosphorylation of cellular proteins by the viral protein kinases has also been described.⁶⁴² As late proteins, the accumulation of viral protein kinases would depend on the synthesis of ICP0.

MICRORNAS

A total of 16 and 17 microRNAs have been discovered for HSV-1 and HSV-2, respectively, many of which are encoded proximal to or within the *LAT* locus; however, some arise from the S component inverted repeated region.^{240,521,1126,1128} The first of these discovered—HSV-1 miR-H1—is expressed relatively abundantly in productively infected cells as a late gene.²⁴⁰ HSV-1 microRNAs miRH2 through H8 and miRH11 through H17, as well as HSV-2 miRH2 through H7, H9, H11 through H13, and H19 through H25, are also expressed during productive infection.⁵²¹ There is limited information on targets of HSV microRNAs and even less on their biological functions because a limited number of mutant viruses have thus far been constructed and characterized. HSV miR-H2, -H3, and -H4 are perfectly complementary to HSV mRNAs encoded on the opposite strands and can down-regulate the expression of proteins encoded by these mRNAs when expressed in transfected cells. HSV-1 miR-H2 inhibits ICP0 expression of the immediate-early protein ICP0,¹¹⁶⁸ and HSV-2 miRH3 inhibits ICP34.5 expression in transfected cells¹¹²⁶ and in infected cells.¹¹²⁸ The seed region of HSV-1 miR-H6 has complementarity with the mRNA encoding the immediate-early protein ICP4 and can down-regulate its expression in transfected cells.¹¹⁶⁸ In contrast, the HSV-2 miR-H6 does not down-regulate ICP4 expression in transfected or infected cells.¹¹²⁷ Repression of viral transcriptional activators ICP0 and ICP4 by microRNAs may be important for repression of HSV-1 productive-cycle gene expression, although it remains to be shown that these effects are exerted in virus-infected cells.

Viral DNA Replication

Production of progeny virus requires the amplification of the input viral DNA genomes for assembly into progeny viral particles. Many of the viral β proteins prepare the infected cell for or are directly involved in viral DNA replication through targeting and

assembly of viral proteins into intranuclear structures, where viral DNA replication initiates (prereplicative sites) and where viral DNA replication proceeds (replication compartments; see Fig. 60.4), and for enhancement of levels of nucleotide precursors for viral DNA synthesis in resting cells. As described earlier, the input viral genomes target to the nuclear periphery soon after entry into the nucleus. Following α and β gene transcription from the viral DNA molecules, likely at these sites, the viral DNA replication proteins then localize to these genomes on the nuclear periphery to form structures called *prereplicative sites*.^{255,909} Prereplicative sites near ND10 sites are the sites of initial viral DNA replication,¹¹⁷⁴ and these structures grow into replication compartments as DNA replication proceeds.²⁵⁵ The replication compartments enlarge, merge, and fill the nucleus, concomitant with peripheral margination of the host chromatin,^{763,1051} suggesting that the HSV replication compartments displace the cellular chromatin from internal sites in the nucleus.

The mechanism of HSV DNA replication has not been fully elucidated, although the origins of viral DNA replication and essential viral gene products have been defined. The major DNA replicative products inside infected cells are long “head-to-tail” concatemers containing the four sequence isomers described earlier,⁴⁹¹ and the mechanisms of viral DNA synthesis need to accommodate this observation.

It is generally accepted that HSV DNA replication is a two-stage process involving initiation by binding of the HSV U_L9 origin binding protein to an origin and formation of the replication complex, which replicates the molecule through an intermediate such as a Cairns circle or theta molecule (Fig. 60.10) in a process that yields circular progeny DNA molecules. At a later time, there is a switch to an origin-independent replication mechanism. Both rolling circle¹⁰⁶ and recombinational^{812,1262} mechanisms have been proposed for the second stage of HSV DNA synthesis. Rolling circle mechanisms have been the favored mechanism because (a) rolling circle replication on preformed templates has been achieved *in vitro*,^{327,911} and (b) it is simpler to see how this mechanism could generate the tandem repeats of viral DNA in defective viral genomes.^{77,1194} These two types of mechanisms are not mutually exclusive, however, because models involving both rolling circle replication and recombination have also been proposed.⁹⁵³

Seven viral proteins are required for viral DNA replication. The seven gene products are the viral DNA polymerase catalytic subunit (U_L30) and its processivity factor (U_L42); an origin-binding protein (U_L9); the ICP8 single-stranded DNA-binding protein (U_L29); and the helicase-primase complex of three proteins—U_L5, U_L8, and U_L52.^{173,221,904,1275} Host cell factors (HCFs) are presumably also involved in viral DNA synthesis, although these have not been identified, in large part because HSV DNA replication involving origin-dependent initiation and synthesis has not been achieved *in vitro*. Nevertheless, host enzymes, including the DNA polymerase α -primase, DNA ligase, and topoisomerase II, are probably also required. Early immunofluorescence studies showed that cellular RPA single-stranded DNA binding protein, PCNA, Rb, p53, DNA ligase 1, and pol α co-localized with ICP8.¹²⁵⁷ Inhibition of topoisomerase II prevents efficient replication of HSV-1 DNA,⁴¹⁵ possibly by preventing decatenation of newly synthesized daughter molecules. Proteomic studies showed that numerous cellular DNA repair, DNA damage response, and

FIGURE 60.10. Diagram of a model of herpes simplex virus DNA replication. **1:** Input DNA is circularized upon entry into the nucleus. **2:** U_L9 (the origin binding protein) initially binds to specific elements in the origin (either *oriL* or *oriS*) and begins to unwind the DNA. U_L9 then recruits ICP8 (the single-stranded DNA binding protein) to the unwound single-stranded DNA. **3:** U_L9 and ICP8 recruit the five remaining viral DNA replication proteins to the replication forks. **4:** The helicase-primase proteins and the viral polymerase complex assemble at each replication fork for initial rounds of theta form replication. **5:** Replication switches from theta to rolling circle mode by an unknown mechanism. U_L9 is not necessary for rolling circle replication, as it is not origin dependent. **6:** Rolling circle DNA replication produces long head-to-tail concatamers of viral DNA, which are cleaved into monomeric molecules during packaging. (Copyright Lynne Chang and David Knipe.)

recombination proteins are associated with ICP8¹¹³² and localize to replication compartments.^{1132,1261} Mre11, Rad50, Nbs1, RPA, MSH2, BRCA1, BLM, WRN, DNA ligase 1, RAD51, and Ku86 are located in prereplicative sites and replication compartments.^{393,648,1043,1132,1257,1261} Cells defective for WRN

helicase¹¹³² or Mre11 or ataxia telangiectasia mutant (ATM)⁶⁴⁸ show reduced HSV replication; thus, these proteins promote viral replication in some way. It is not known if these host proteins are involved in viral DNA replication at this time.

The origins of viral DNA synthesis were identified through mapping of sequences found in defective viral genomes^{350,667} and sequences needed for plasmid DNA amplification in transfection studies.^{761,1195,1231} The origins include *oriS*, a sequence located in the *c* sequences bounding the S component and therefore present in two copies in the viral genome, and *oriL*, a sequence located between the divergent transcription units of the genes for two viral DNA replication proteins: ICP8 and DNA polymerase. Both *oriL* and *oriS* are palindromic structures, with *oriL* being a 144-bp palindrome and *oriS* being a shorter palindrome of 45 bps that center around AT-rich regions of 20 and 18 bps, respectively. Inverted repeats that contain binding sites for the U_L9 protein, called box I, are located on either side of the AT-rich region of *oriL*. *oriS* contains a box I sequence to the 5' side of the AT-rich region and a similar sequence with a tenfold lower binding affinity for U_L9, called box II, located 3' to the AT-rich region. In *oriL*, the box I sequences are flanked by another homologous sequence, box III, which has greatly reduced affinity for U_L9. *oriS* contains one copy of box III flanking the 5' box I. *OriL* is notoriously unstable when cloned into plasmids, thus little genetic analysis has been performed on this sequence. Box I is required for *OriS* function, and mutations in box II greatly reduce DNA replication. Although box III shows weak binding to U_L9 *in vitro*, mutations in box III reduce replication by approximately fivefold in transfection assays.

The reason(s) for three potential origins of replication in the viral genome are not apparent at this time. Neither origin is specifically required for viral replication. A mutant virus with a deletion in *oriL* is viable and showed normal burst size and latent infection.⁸⁸¹ In addition, mutant viruses with both *oriS* sequences deleted showed at most a fourfold reduction in viral yields and only slightly delayed viral DNA synthesis.⁴⁸³ It has been suggested that one of these origins may represent vestigial origins from the L and S components of the viral genome,⁹⁵⁹ and that one of these origins, *oriL*, may function in reactivation from latent infection.⁴²⁰ One study found that an *oriL* mutant virus shows reduced replication in mouse tissues and reduced reactivation from latent infection.⁵⁹ Thus, *oriL* may be required for DNA replication in certain tissues; alternatively, the expression of the bounding *U_L29* and *U_L30* genes may be affected in these tissues.

Viral DNA Replication Proteins

The seven essential HSV DNA replication proteins are reviewed in detail elsewhere.^{106,955,1219}

DNA POLYMERASE

The HSV DNA polymerase has been studied extensively, partly as a result of its potential as a target for antiviral drugs. A new DNA polymerase activity was detected in HSV-infected cells in the 1960s; however, formal genetic proof that it was virus encoded was not provided until the late 1970s, when ts and drug-resistant mutations affecting the properties of the polymerase were isolated and mapped to the viral genome. The HSV DNA polymerase holoenzyme is a heterodimer of the 136 kDa U_L30 protein complexed with the 65 kDa U_L42 protein.

The U_L30 protein contains the polymerase activity, and it contains three sequence motifs that are homologous and align with sequence motifs I, II, and III of other DNA polymerases. The U_L30 protein also has an intrinsic 3′-5′-exonuclease activity, which can serve as a proofreading activity. The crystal structure of U_L30 defined the pre-NH2 domain, NH2-terminal domain, 3′-5′-exonuclease domain, polymerase palm subdomain, finger subdomain, and thumb subdomain.⁶⁶⁰

U_L42 increases the processivity of the U_L30 DNA polymerase activity. The structure of U_L42 protein bound to the C-terminal fragment of U_L30 has been determined,¹³²⁴ and U_L42 is unusual in binding DNA directly as a monomer rather than as a toroid wrapping around the DNA as other processivity factors do. U_L42 is capable of linear diffusion along DNA despite its high-affinity binding to DNA.⁹¹⁸ The interaction between U_L30 and U_L42 is essential for viral DNA replication *in vivo*, and these interaction sites are being investigated as possible targets for antiviral compounds. U_L42 also interacts with cdc2 and topoisomerase II α , as noted previously.

The HSV DNA polymerase interacts with a broader range of deoxynucleoside triphosphates than cellular polymerases, and this has allowed the development of compounds that specifically inhibit the viral DNA polymerase. These compounds are discussed later and in Chapter 13.

ORIGIN BINDING PROTEIN U_L9

The U_L9 origin binding protein forms a homodimer and binds specifically to the sequence CGTTCGCACTT. U_L9 also has ATP-binding and DNA helicase motifs that are essential for viral replication. Binding of U_L9 to origin sequences induces a bend in the DNA and formation of a single-stranded stem-loop structure. The addition of the HSV single-strand DNA binding protein, ICP8, allows U_L9 to unwind Box I of *oriS* if an 18-nucleotide single-strand tail is present 3′ to Box I. Thus, ICP8 may provide a single stranded DNA region in the AT-rich region, from which U_L9 can separate the strands. As an origin binding protein, U_L9 would play a role in origin-dependent synthesis originating from the circular molecules, but once synthesis has converted to a rolling circle or recombination-based mode, U_L9 would presumably not be needed as an origin binding protein.

SINGLE-STRANDED DNA BINDING PROTEIN, ICP8, U_L29

ICP8 is an abundant protein in HSV-infected cells and was first identified as the major DNA-binding protein in HSV-infected cells. ICP8 binds preferentially to single-stranded DNA, and this single-stranded DNA binding function is essential for viral DNA replication. ICP8 also exhibits a helix-destabilizing activity but can also catalyze the renaturation of complementary single strands. Probably as a consequence of the latter two activities, ICP8 can promote strand transfer, which may contribute to the high frequency of homologous recombination observed in infected cells. In addition to its single-stranded DNA binding function, ICP8 interacts with several other viral DNA replication proteins, as evidenced by its physical interaction and stimulation of U_L9 helicase activity; stimulation of the U_L5/8/52 helicase activity; functional interaction with DNA polymerase; and co-immunoprecipitation with U_L9, U_L8, and pol proteins. Consistent with these numerous interactions, ICP8 is required for localization of other viral proteins and cellular proteins to prereplicative sites in infected cell nuclei. As a result of its size and numerous protein interactions,

ICP8 is likely to play a scaffold role in assembly of HSV DNA replication complexes. The crystal structure of a 60-residue C-terminal deletion form of ICP8 showed a novel fold consisting of a large N-terminal domain (residues 9–1,038) and a small C-terminal domain (residues 1,049–1,129).⁷⁰⁷ The overall structure provided a potential groove containing aromatic and basic amino acid residues that could serve as the single-stranded DNA binding site. ICP8 possesses strand-melting¹⁰⁷ and strand-annealing activities³⁰⁶ and has been reported to mediate limited strand exchange.^{112,811} A recent study has also shown that ICP8 can promote strand invasion.⁸¹²

DNA HELICASE–PRIMASE COMPLEX

The DNA helicase–primase complex, which contains the protein products of the *U_L5*, *U_L8*, and *U_L52* genes, was first identified as a helicase activity from infected cells. The complex unwinds short oligonucleotides annealed to single-stranded M13 DNA in the 5′ to 3′ direction. A complex of U_L5 and U_L52 has DNA-dependent ATPase, helicase, and primase activities, thus this constitutes the core enzyme. U_L8 promotes the nuclear localization of this complex and, in concert with ICP8, stimulates optimal activities of the core enzyme. Therefore, the holoenzyme can unwind a 2.3-kbp nicked plasmid in the presence of ICP8. The primase activity produces oligoribonucleotides 6 to 13 bases in length, and the preferred template sequence is 3′AGCCCTCCCA, with synthesis initiating at the first C.

Model for Herpes Simplex Virus DNA Replication

Based on the available information, a model for HSV DNA replication (see Fig. 60.10) has been formulated.¹⁰⁶ The first steps in HSV DNA replication involve the binding of U_L9 protein and/or ICP8 to the origin sequences and the looping and distortion of the origin sequences by U_L9. ICP8 then binds to U_L9 and/or single-stranded DNA regions, and the U_L9 helicase activity unwinds the DNA. The helicase–primase complex is then recruited to the origin by interactions with U_L9 and/or ICP8. Leading strand synthesis involves the unwinding of the DNA and synthesis of a primer by the HSV helicase–primase complex, from which leading strand synthesis can be accomplished by the HSV pol-U_L42 holoenzyme. Alternatively, primers may be synthesized by the cellular polymerase α -primase. Lagging-strand synthesis is then accomplished by primer synthesis and pol-U_L42 extension of the DNA strand. Because the progeny DNA is largely in the form of head-to-tail concatemers,⁴⁹¹ it is believed that although synthesis initiates from the theta form, it is rapidly converted to a rolling circle replicative mechanism, by which concatemeric molecules can be synthesized.

Accessory Viral Gene Products Involved in Viral DNA Synthesis and Postsynthesis Modification

Several other HSV gene products, including the TK, deoxyuridine triphosphatase (dUTPase), ribonucleotide reductase, and uracil DNA glycosylase, are not essential for viral replication in cultured cells but are likely to be essential for nucleotide metabolism and viral DNA synthesis and repair in resting cells, such as neurons. The corresponding host cell enzymes are not expressed in resting cells, and it is likely that the virus has evolved to encode these enzymes to optimize its own DNA synthesis in these cells.

THYMIDINE KINASE

The TK enzyme was first identified as a deoxythymidine kinase, giving rise to its name. In fact, it phosphorylates pyrimidines and even purine nucleosides. In addition, it has a thymidylate activity. Its broad substrate specificity allows it to phosphorylate nucleoside analog molecules, which then can serve as antiviral compounds. The HSV TK consists of a homodimeric complex of the U_L23 protein, the structure of which has been solved. HSV presumably encodes a TK activity to provide nucleoside triphosphate precursors for DNA synthesis in resting cells such as neurons, where the cellular enzyme is not expressed (see later discussion). The viral enzyme leads to an increase in dTTP pools relative to that seen in uninfected cells or early in infection. This complicates the use of radioactive thymidine for labeling of viral DNA synthesis in infected cells, because the specific activity of the labeled DNA will be lower at later times of infection.

DEOXYURIDINE TRIPHOSPHATASE

HSV dUTPase, a monomer of U_L50 protein, hydrolyzes dUTP to dUMP and pyrophosphate, preventing the incorporation of uracil into DNA. HSV-1 dUTPase mutants are attenuated for neurovirulence, neuroinvasiveness, and reactivation from latency.⁹⁰⁸

RIBONUCLEOTIDE REDUCTASE

Ribonucleotide reductase catalyzes the reduction of ribonucleoside diphosphates to the corresponding deoxyribonucleoside diphosphate. The HSV enzyme consists of a complex of the U_L39 and U_L40 proteins as an $\alpha_2\beta_2$ tetramer.⁴⁶ The HSV ribonucleotide reductase is not subject to the same allosteric controls as the cellular enzyme; thus, the HSV enzyme is not inhibited by the increased dTTP pools in HSV-infected cells. The HSV ribonucleotide reductase is required for viral replication in nondividing cells. The large subunit has an intrinsic autophosphorylating kinase activity that is separable from the ribonucleotide reductase activity.

URACIL DNA-GLYCOSYLASE

The enzyme uracil DNA-glycosylase removes uracil bases from DNA—bases that arise in DNA by the deamination of cytosine to form uracil by the cleavage of the N-glycosidic bond linking uracil to the deoxyribose sugar. The site is then repaired so that a mutagenic event converting a G-C base pair to an A-T base pair does not occur. The HSV enzyme is encoded by the U_L2 gene.¹⁵⁶

ALKALINE NUCLEASE

The enzyme alkaline nuclease is a phosphoprotein encoded by the U_L12 gene.⁸⁹⁵ It has endo- and exonuclease activities and is active at pH 9 to 10. As described later, this nuclease plays a role in DNA maturation and encapsidation. The HSV nuclease may be required to resolve concatenated viral DNA for packaging. U_L12 interacts with ICP8,¹¹⁴⁰ possibly to allow the nuclease to act directly on viral replication intermediates or products. U_L12 and ICP8 facilitate strand exchange *in vitro*,⁹³⁰ and ICP8 stimulates nuclease activity by increasing processivity of the enzyme.⁹³¹

Viral DNA Recombination

Homologous recombination is very efficient in HSV-infected cells, and multiple cross-over events between co-infecting viral genomes are apparent in progeny viruses, even between HSV-1

and HSV-2 genomes. Viral DNA replication is required for this high level of homologous recombination, and the time courses of DNA replication and recombination are parallel in cells transfected with viral *oriS* plasmids. The mechanism by which replication of the DNA promotes recombination is not known; however, the single-stranded regions or the concatemeric molecules might be targets for cellular or viral recombination machinery. In addition, ICP8 is known to promote strand transfer, thus it might play a role in recombination in infected cells.

Inversion of the genomic L and S segments also involves recombination between the terminal repeats and the internal inverted repeats. As described earlier, HSV virion DNA contains four populations of molecules bearing the four orientations of the L and S components of the genome. This novel feature of the genome of HSV and certain other, but not all, herpesviruses (see Chapter 59) has long intrigued the field, and interest has been further piqued by the observation that viruses without internal repeats replicate well in continuous cell lines but poorly in primary human cells.^{498,879} These mutant viruses are nonpathogenic, suggesting that the internal inverted repeats play a key role in primary human cells and *in vivo*. The L–S junction sequences—in particular, the *a* sequences—promote high-efficiency inversion in that insertion of a copy of these sequences at other sites in the genome leads to inversion of these sequences. Duplication of certain other viral sequences at a second site in the viral genome can lead to additional inversion events; however, these events appear to be less efficient than *a* sequence-mediated inversion. The 95bp Uc-DR1 sequence is specifically required for inversion at the *a* sequence, although it remains to be determined if this event involves site-specific recombination or a hot spot for recombination.

ACTIVATION OF HOST DNA REPAIR PATHWAYS

The interactions of HSV with DNA repair pathways are complex. The presence of nicks and gaps in the incoming viral DNA is likely to result in activation of DNA repair pathways, as discussed above. Consistent with this, HSV infection has been shown to activate the host DNA damage repair pathway.^{648,1261} Some of this host response may be due to parental viral DNA, but the peak response requires and/or coincides with viral DNA replication.^{648,1261} Phosphorylation of ATM is observed as early as 0.5 hpi but increases until 8 hpi during the time of viral DNA synthesis.⁶⁴⁸ Thus, DNA damage sensors may recognize the input viral DNA, yet the optimal response involves newly replicated DNA. HSV infection activates the ATM-dependent signaling pathway while it inhibits the DNA-PKcs and ATR (ATM and Red 3-related)-dependent pathways.^{7,28–30,648,762,847,1261} To counter the inhibitory effects of DNA repair mechanisms on viral replication, ICP0 promotes the degradation of RNF8 and RNF168, which are mediators in the ATM pathway.^{649,650} The effects of the DNA repair components on HSV replication are complex in that some components are inhibitory to viral replication and others stimulate viral replication.^{648,1132} It is conceivable that whereas HSV inhibits the DNA repair pathways, it has co-opted DNA repair mechanisms for its own genome replication, much as the host cell uses DNA repair mechanisms as part of its genomic synthesis.⁷¹⁹

Viral Nucleocapsid Assembly

Following their synthesis, the γ capsid proteins localize into the infected cell nucleus, where capsid assembly occurs. Empty

shells containing an internal scaffolding are assembled first, then viral DNA is inserted or encapsidated into the capsid concomitant with loss of the scaffolding. Our knowledge of the mechanisms of assembly of the HSV capsid has come from several lines of experimentation: (a) study of infected cell complexes and structures, (b) assembly of capsid structures from extracts of insect cells infected with baculoviruses expressing HSV capsid and scaffolding proteins, (c) study of protein localization using immunofluorescence, and (d) genetic analysis of the functions of capsid and scaffolding proteins. Each of these approaches has contributed important information to our understanding of this process.²²⁴

Immunofluorescence studies have shown that the initial stages of assembly of at least some capsid proteins occur in the cytoplasm. VP5, the major capsid protein that makes up the hexons and pentons, VP26 located on the outer tips of hexons, and triplex protein VP23 are incapable of nuclear localization on their own. Thus, complexes involving these proteins may form in the cytoplasm and localize into the nucleus. VP5 may be carried into the nucleus by triplexes or by pre-VP22a, a scaffolding protein. VP26 localizes into the nucleus only when it is expressed with both VP5 and VP19C or pre-VP22.

Electron microscopic studies have shown that the final assembly of capsids occurs in the nucleus. Three types of capsids—A, B, and C—have been identified in infected cell nuclear extracts using sucrose density gradient ultracentrifugation.³⁷⁵ All three types of capsids are approximately 120 nm in diameter with an outer shell consisting of hexons and pentons made up of VP5, the major capsid protein. The capsomers are linked by triplex structures comprised of the two minor capsid proteins VP19C (*U_L38*) and VP23 (*U_L18*), each complex on average consisting of one molecule of VP19C and two molecules of VP23. C capsids contain viral DNA and a heterodimer of viral proteins, *U_L25* and *U_L17*, that form the capsid vertex-specific component (CVSC).^{210,1156} This was originally thought to be specific for C capsids¹¹⁶⁴; however, this complex was also seen in reconstructions of all three forms of capsids,²¹⁰ albeit at perhaps at lower amounts in A- and B capsids,²²⁴ thus the more general CVSC name has been used. C capsids mature into infectious virions by budding through the nuclear membrane. B-capsid cavities are filled with VP22a and VP21, the cleaved forms of the scaffolding protein, and a viral protease, VP24. The scaffolding protein, but not the protease, is removed upon encapsidation of DNA to form C capsids. A capsids are not filled with DNA or scaffolding protein and are believed to be abortive forms that result from failed attempts to package DNA.

Scaffolding Proteins and Maturation Protease

Although the other capsid proteins are encoded in separate ORFs and transcriptional units (see Gene List.), the scaffolding proteins and maturational protease are encoded by the overlapping *U_L26* and *U_L26.5* genes, which encode a complex set of gene products involved in formation of a core for capsid assembly and for capsid maturation. The *U_L26* gene encodes a 635 amino acid residue precursor protein with an intrinsic protease activity that cleaves either autoproteolytically or *in trans* after residues 247, the R site, and 610, the M site, in the precursor molecule. The amino terminal 247-residue fragment is VP24, which retains protease activity. The fragment from residues 248 through 610 is VP21, which can serve as a scaffolding for capsid assembly. The *U_L26.5* gene mRNA initiates

within the *U_L26* gene and encodes a protein that is read in the same reading frame as *U_L26*. The *U_L26.5* protein, pre-VP22a, is equivalent to the C-terminal 329 residues of *U_L26* and is also subject to cleavage by the *U_L26* protease at the M site near its C-terminus to give a 304-residue protein, which is known as VP22a. Of the *U_L26* and *U_L26.5* gene products, the pre-VP22a protein functions as the major scaffolding protein for capsid assembly. The carboxy-terminal 14 residues of pre-VP22a (and VP21) are recognized by VP5 during capsid assembly.

The protease activity encoded by the *U_L26* gene is a serine protease⁶⁵⁶ whose activity is required for virus assembly.³⁵⁸ Cleavage at the R site is required for viral infectivity,⁹⁴² and cleavage at the M site is believed to be involved in release of the scaffolding protein from the capsid interior. Mutagenesis studies have identified two histidines and two glutamic acid residues essential for proteolytic activity; however, a conserved cysteine was dispensable in the 247 amino acid polypeptide.^{655,656} Proteases have been targets for drug development in many biological systems, and considerable effort has been devoted to identifying specific inhibitors of the HSV protease as possible antiviral compounds. The crystal structures of the HSV-1 and HSV-2 proteases have been solved.⁴⁶⁶

Capsid Assembly

In the nucleus, the VP5–pre-VP22a complexes come together as a result of self-interactions of pre-VP22a molecules. The triplex proteins are then added to form a partial capsid. As hexons and pentons are added, the partial capsid assembles into a round procapsid.⁸⁰⁰ Although it was originally proposed that the portal complex of 12 *U_L6* protein molecules is assembled onto the procapsid through interactions of *U_L6* with *U_L26.5* protein,⁸⁰⁴ the portal may be the nidus upon which the rest of the capsid is built into a sphere,⁷⁹⁹ because that would ensure one portal per capsid. The procapsid structures undergo a structural transformation and become angular and polyhedral.^{203,1147,1162} It is likely that DNA is encapsidated into procapsids as in the model of Newcomb et al.⁸⁰⁰

Much of our knowledge of the capsid assembly process has come from analyses of structures formed in insect cells infected with baculoviruses expressing HSV capsid or scaffolding proteins^{1129,1148} and in extracts from these infected cells.⁸⁰² In these studies, a series of baculovirus recombinants were constructed that each express one capsid or scaffolding protein, and B capsids with normal structure were formed when insect cells were co-infected with viruses encoding the VP5, VP19C, VP23, and *U_L26* or *U_L26.5* gene products. When the *U_L26* and *U_L26.5* genes were left out, no intact capsids were formed, indicating that these gene products are needed to form a scaffold structure around which the shell proteins could form a closed capsid. Similar phenotypes were observed with HSV strains in which the *U_L26* and *U_L26.5* genes were mutated.²⁶⁹ In the baculovirus studies, when the *U_L26* gene was omitted, large-cored B capsids were observed because in the absence of the maturational protease, the *U_L26.5* protein is not cleaved. Thus, cleavage of the *U_L26.5* scaffolding protein leads to condensation of the core. When the *U_L26.5* gene was omitted, intact capsids were observed, but no core structure was apparent. Viruses mutated for *U_L26.5* can still produce infectious virus; however, progeny virus yields are reduced by 10²- to 10³-fold relative to wild-type virus.³⁵⁸ These data indicate that the *U_L26* gene products can serve as scaffolding proteins, although they form a different

core and one that is not as effective as cores containing *U_L26.5* gene products.

In vitro assembly of B capsids can occur when extracts from insect cells individually infected with baculoviruses expressing VP5, VP19, VP23, *U_L26*, and *U_L26.5* gene products are mixed and incubated.⁸⁰⁰ *In vitro* assembly of procapsids requires only the purified viral components VP5, VP19C, VP23, and a scaffolding protein, thus assembly of procapsids does not require any cellular proteins.⁸⁰¹ It has been hypothesized that procapsids may be involved in the early stages of viral DNA packaging, much like the prohead structures of bacteriophages.⁴⁶⁰

Assembly of capsids takes place at early times of infection within replication compartments at sites near those of viral DNA replication^{203,256} and at later times in certain cell types also in nuclear structures called *assemblons*.^{791,1216} It is likely that the next step in viral replication—encapsidation—occurs in replication compartments.

Encapsidation of Viral DNA

Encapsidation of HSV DNA involves a process in which the terminal L components of HSV progeny concatemeric DNA molecules¹³¹⁰ are fed into capsids in an energy-dependent process,²⁵⁰ and the concatemers are cleaved into unit-length monomers by a linked process, as originally shown for pseudorabies virus. Insertion of the L component first would lead to packaging of the S component last, consistent with it being the first to exit the capsid.⁷⁹⁷ This process is not well defined; however, the concatemeric progeny molecules are likely fed into the capsid concomitant with displacement of scaffolding molecules VP21 and VP22a from the capsid. The viral DNA concatemer is thought to be cleaved upon encapsidation of a length of DNA that fills the capsid or when a *headful* (a term that originated with bacteriophage head assembly) of DNA has been inserted. Varmuza and Smiley¹¹⁸⁷ first mapped signals for cleavage and packaging within the *U_b* and *U_c* domains of the *a* sequences, and Deiss et al²⁶¹ mapped these precisely and designated the two DNA packaging elements as *pac1* and *pac2*, respectively.

Concatemers are cleaved into unit-length molecules during packaging. Cleavage occurs site specifically within the DR1 sequences of the *a* sequences⁷⁵⁹ and involves two site-specific breaks at defined distances from the *pac1* and *pac2* packaging signals.^{261,1059,1187} The maturational process duplicates the sequences between these two cleavage sites so that cleavage at sites bearing only one *a* sequence leads to two molecules with terminal *a* sequences.^{262,1059,1187} Several models have been proposed to explain the cleavage and metabolism of viral DNA during encapsidation.^{261,1187} In general, these models propose that a packaging complex binds to the DNA and scans for a *U_c* sequence. Cleavage occurs at a DR1 element proximal to the *U_c* sequence, then the packaging complex will scan the DNA as it is packaged until a directly repeated junction is encountered. Alternatively, two cleavages at the L and S termini will produce a monomer molecule. The amplification of the *a* sequence may occur by staggered nick-repair or gene conversion. The terminal *a* sequence generated by the cleavage may be recombinogenic in either a single- or double-stranded form and promote inversions and/or *a* sequence amplification. In any event, the process must yield the virion form of the genome with an L terminus containing one or more *a* sequences and a 3' single base overhang, a unit-length genome with an L and S compo-

nent, and an S terminus containing a single *a* sequence and a 3' single base overhang.

Encapsidation of viral DNA requires at least seven viral gene products, including *U_L6*, *U_L15*, *U_L17*, *U_L25*, *U_L28*, *U_L32*, and *U_L33*,²²⁴ although the mechanism(s) of this process remain to be defined. As described earlier, a complex of 12 *U_L6* proteins serves as the portal at one capsid vertex as the portal for entry of viral DNA into the capsid.⁸⁰³ A complex of *U_L15*, *U_L28*, and *U_L33* proteins is proposed to serve as the terminase, which cleaves the concatemeric DNA into monomers when a monomer is packaged into the capsid. The *U_L28* protein binds to the *pac1* cleavage-packaging sequence,⁷ a sequence needed for termination of DNA packaging.⁴⁵⁴ The *U_L15* protein has homology to the bacteriophage T4 terminase large subunit, including a Walker A motif, which is present in a wide range of ATPases, including bacteriophage terminases.²⁵³ The structure of a cytomegalovirus (CMV) homolog suggests that the *U_L15* homologs are a family of proteins with nuclease activity mediated by an RNase H-like domain.⁷⁸¹ *U_L33* is assembled in the complex with the two proteins⁷⁶ and may reinforce the *U_L28/U_L15* interaction.¹²⁸⁸ Therefore, the complex of the *U_L28* and *U_L15* proteins has the specific DNA-binding and nuclease activities needed for a terminase.^{492,1288,1289} *U_L15* may also have a role in translocation of the DNA into the capsid.¹²⁹¹ *U_L25* seems to be involved in retaining DNA in the capsid,⁷³⁵ possibly by acting as a plug in the C capsid⁸²² or by adding structural rigidity to the capsid. *U_L17* interacts with *U_L25* and is an important part of the CVSC, and its role is probably to make the capsid competent for DNA packaging.^{1017,1156}

Viral Egress

Once the mature nucleocapsid is formed in the nucleus, its route to the extracellular space is a complicated one in that it must traverse the nuclear membranes, cytoplasm, and plasma membrane.⁵⁰⁷ Cell lysis is a very late aspect of HSV infection, thus viral egress must occur through a specialized pathway. At least three general models have been proposed for HSV egress from the infected cell,⁹⁵⁶ including envelopment–de-envelopment–re-envelopment,¹⁰⁵⁴ the luminal pathway,^{510,956} and the nuclear pore egress pathway¹²⁶⁰ (Fig. 60.11).

Although this has been a controversial area, the first model—envelopment–de-envelopment–re-envelopment—is supported by substantial data⁵⁰⁷ and is considered to be the “most prominent model of virion egress”.⁵⁰ The presence in the cytoplasm of filled capsids juxtaposed to curved, invaginated vesicles was first interpreted as evidence of envelopment at cytoplasmic membranes.¹⁰⁸⁷ We will consider this model and then consider the alternative models.

Primary or nuclear envelopment involves the budding of the mature nucleocapsid through the inner nuclear envelope. In the HSV-infected cell nucleus, the marginated host chromatin and the nuclear lamina constitute barriers to the budding of filled capsids through the inner nuclear membrane. To deal with these barriers, HSV infection causes both dispersal of the marginated host chromatin¹⁰⁵¹ and disruption of the nuclear lamina.^{934,1051} Primary envelopment is promoted by the viral *U_L31* and *U_L34* proteins, a complex referred to as the nuclear egress complex (NEC), in that primary envelopment and viral replication are decreased by 10³- to 10⁴-fold with *U_L31* null mutant viruses¹⁷⁹ and 10³- to 10⁵-fold with *U_L34* null mutant viruses in some but not all cell lines.⁹⁶⁵ The *U_L31* null mutant

FIGURE 60.11. Models for egress of herpes simplex virus (HSV) from the host cell. Shown are the proposed pathways for maturation of filled capsids from the nucleus to the exterior of the infected cell. **I:** In the dual envelopment pathway,^{748,1054,1087} nucleocapsids undergo primary envelopment at the inner nuclear membrane, become de-enveloped at the outer nuclear membrane, undergo secondary envelopment at cytoplasmic membranes, and then are transported in vesicles to the plasma membrane where fusion of the vesicle with the plasma membrane releases the virion to the extracellular space. **II:** In the luminal model,³¹⁵ the nucleocapsid is enveloped at the inner nuclear membrane, enters a vesicle at the outer nuclear membrane, and is then transported to the plasma membrane where the virion is released. **III:** In the nuclear pore model,¹²⁶⁰ filled capsids exit the nucleus through enlarged nuclear pores and become enveloped by budding into cytoplasmic vesicles, and the virion is transported to the plasma membrane where the virion is released. Wild et al¹²⁶⁰ have proposed a dual pathway for egress, in which HSV uses the luminal pathway at early times of infection but the bulk of extracellular virus is formed by the nuclear pore pathway at late times of infection. (Copyright Lynne Chang and David Knipe.)

also showed a defect in viral DNA replication¹⁷⁹; therefore, U_L31 may play a role in that process as well as envelopment. U_L34 is a type II integral membrane embedded in the inner nuclear membrane, and U_L31 is a nucleoplasmic phosphoprotein that is retained at the inner nuclear membrane through its interaction with U_L34.

U_L31 and U_L34 may promote the disruption of the nuclear lamina in several ways: (a) U_L31 and U_L34 bind directly to lamin A/C and modify the conformation of these lamins,⁹³⁴ (b) recruitment of protein kinase C to the nuclear lamina and phosphorylation of lamin B,⁸⁴⁴ and (c) recruitment of the viral U_S3 protein kinase to the nuclear lamina and phosphorylation of lamin A/C.⁷⁶⁹ U_L31 and U_L34 are also required for the dispersal of the marginated cellular chromatin,¹⁰⁵¹ which may be an indirect effect of disruption of the nuclear lamina, to which cellular chromatin is tethered.³⁹⁶ The contribution of these two proteins differ in different cells because there are differing genetic requirements for U_L31, U_L34, and U_S3 for primary envelopment in different cell types.

Budding of mature nucleocapsids involves binding of the capsid to the inner tegument proteins—VP1/2, U_L37, VHS, VP22 and VP16—which are associated with the inner tails of viral glycoproteins. Full capsids or C capsids are preferentially enveloped and move into the cytoplasm.¹¹⁹⁵ As discussed earlier, C capsids contain a complex of U_L17 and U_L25 at the vertices that lock the filled capsid structure in place. A recent study has shown that the U_L17/U_L25 complex binds to U_L31¹²⁸⁷; there-

fore, an attractive mechanism for the selective envelopment of C capsids is that the U_L17/U_L25 marked capsids bind to U_L31 at the inner nuclear membrane to initiate primary envelopment. The NEC may also recruit HSV glycoproteins to the inner nuclear membrane for primary envelopment.¹²⁶⁴ HSV glycoproteins gM, gB, gH/gL, and gD are found in the inner nuclear membrane and in perinuclear virions, yet their role in primary envelopment has not been defined.

De-envelopment, the next step in egress in this pathway, involves the fusion of the envelope of the virion in the perinuclear space with the outer nuclear membrane, releasing the capsids and tegument into the cytoplasm. The mechanism of this fusion process is not known; however, the viral gB and gH/gL glycoproteins are required for de-envelopment, as shown by a gB/gH double mutant virus.³²⁸ It is interesting that the single mutants affected egress to a much lesser extent. U_S3, which encodes a viral kinase, promotes de-envelopment through phosphorylation of gB and U_L31.^{770,1269} Although the gB⁻ gH⁻ gL⁻ mutant virus shows increased numbers of enveloped particles in the perinuclear space, extracellular virions are reduced by much less; thus, there may be other mechanisms for egress that are independent of these viral glycoproteins. Definition of the de-envelopment mechanism requires identification of receptors in the inner surface of the outer nuclear membranes that would enable membrane fusion, and hence de-envelopment, to take place.

Secondary envelopment involves the budding of tegument-coated capsids into cytoplasmic membranes, possibly including

the Golgi apparatus, the *trans*-Golgi network (TGN), and endosomes, producing infectious virions within a vesicle. HSV has been reported to undergo secondary envelopment at sites coincident with markers of the TGN¹¹⁰⁸; however, HSV infection leads to reorganization of cytoplasmic membranes so that markers of Golgi, TGN, and endosome membranes are spread throughout the cytoplasm and this effect varies among different cell lines.^{149,1267} Budding may occur into multivesicular bodies (MVBs), as shown by the requirement for MVB machinery such as Vps4 and Vps24 for viral assembly or egress.^{145,239}

Transport of virions to the surface involves normal exocytosis mechanisms carrying vesicles containing HSV particles to the plasma membrane, and fusion of the vesicle membrane with the plasma membrane leads to release of the virions to the exterior of the host cell. HSV infection may inhibit TGN recycling loops so that vesicle flow is largely from the TGN to the plasma membrane, thereby actively promoting its own release from cells.

The envelopment–de-envelopment–re-envelopment egress pathway seems to be a very complex process, and many aspects such as the energetics of the process and the de-envelopment receptor remain to be defined. However, evidence supporting the dual envelopment egress pathway includes the following: (a) the U_L31 and U_L34 proteins are present in perinuclear virions but not in extracellular virions^{682,935}; (b) the lipid composition of extracellular virions resembles that of cytoplasmic rather than nuclear membranes¹¹⁷⁹; and (c) mutant forms of gD that are retained in the endoplasmic reticulum are present in virions accumulating at the nuclear membrane but not in extracellular virions, consistent with this model.¹⁰⁵⁴

The second model—luminal secretion—was originally based on the observations that capsids are enveloped at the inner nuclear membrane, that enveloped capsids are frequently contained in perinuclear vesicles, and that these transport vesicles fuse with the plasma membrane and release enveloped capsids into the extracellular space.³¹⁵ Although this pathway is attractive in being simpler than the dual envelopment model, as discussed earlier, the lipid content of extracellular virions is similar to cytoplasmic membranes rather than nuclear membranes, arguing against this model.

As the basis for the third model of egress—nuclear pore egress—Wild et al¹²⁶⁰ reported that the nuclear pores of HSV-infected cells become enlarged to a size readily capable of accommodating the egress of unenveloped capsids from the nucleus. They proposed that HSV then exits the cell by budding through cytoplasmic membranes (see Fig. 60.11). According to this model, a fraction of the capsids become enveloped at the inner nuclear membrane and egress the cell through the single nuclear envelopment model. A larger fraction exits the nucleus via the nuclear pore and is enveloped at cytoplasmic membranes. However, other studies have not observed enlargement or other changes in nuclear pores that would allow movement of nucleocapsids to the cytoplasm.⁴⁵⁵ Acceptance of the nuclear pore model hinges on either demonstration of nuclear pore size changes or that capsids interact specifically with nuclear export proteins and that their depletion blocks cytoplasmic envelopment.

Regulators of Membrane Fusion

Certain mutations in specific viral membrane proteins, including gB, U_L20, and gK, lead to aberrant fusion of infected cell

membranes, leading to the syncytial phenotype.^{507,976} U_L20 and gK interact with gB, the fusion protein,¹⁹⁷ consistent with their regulation of membrane fusion. They may also prevent cell-to-cell fusion by interfering with the trafficking of the fusion glycoproteins to and from the plasma membrane, such that their steady-state amounts at the plasma membrane are reduced.⁴⁵ However, the functions of U_L20 and gK are more complex in that they also seem to promote de-envelopment. A U_L20 mutant virus accumulated enveloped particles in the perinuclear space.⁵⁴ gK mutant viruses also showed defects in nuclear and cytoplasmic egress.^{481,496}

Targeting of Virus During Egress

In certain specialized cell types, HSV egress can be targeted. Pathways for release of HSV from neuronal axons will be discussed later. In polarized epithelial cells, for viruses that bud through the plasma membrane, targeting of viral glycoprotein(s) to the apical or basolateral surface defines the site of viral release from the cell. HSV glycoproteins target to the basolateral membranes of polarized epithelial cells.¹⁰⁸⁶ For HSV, with the complex pathways of release described earlier, targeting of viral proteins to specific plasma membrane sites does not direct virus budding to those sites. In fact, HSV egress is targeted to lateral membranes, in particular to cell–cell junctions in polarized epithelial cells, and this process requires the viral gE/gI glycoprotein complex.⁵¹¹ It is believed that the gE/gI complex accumulates in one domain of the TGN and promotes secondary envelopment there and that this domain targets the sorting of virion vesicles to the cell–cell junctions and the basolateral membrane.⁵⁰⁹ The ability of HSV to spread cell to cell is likely to occur via tight junctions in polarized epithelial cells; however, the virus can also spread to other cell types in the presence of antibodies, forming the basis of plaque assays conducted in the presence of antiviral antibodies.^{311,456} This allows HSV to spread *in vivo* from one epithelial cell to another without being neutralized by antiviral antibody. Similar spread to and between neurons may also be possible to a limited extent.

INTRINSIC IMMUNITY, INNATE IMMUNITY, AND ANTI ANTIVIRAL DEFENSES

The host defense mechanisms against HSV are best described in terms of sophisticated arrays of restriction factors, sensors, and preemptive responses arranged all along the pathway of viral replication, from the moment of contact with the cell surface to the point of late viral gene expression. Certain host factors are expressed constitutively and block essential viral replication processes; this restriction has been called *intrinsic immunity*.⁹¹ Other host mechanisms are induced in response to viral infection and are called *innate immune responses* (see Chapter 8). Some of these responses and restrictions act to limit viral replication within the primary infected cell, whereas other responses act to protect surrounding cells from infection. The overall objective is to shut off the invader or, in extremis, to commit suicide for the greater good. Although it is convenient to illustrate the specific defense mechanisms as if they are present and fully operational in every cell likely to be exposed to the virus, this is not the case. For heuristic purposes, it is convenient to segregate host defenses on the basis of the compartment in

which they are located and whether they are triggered before or after the synthesis of viral gene products.

Cytoplasmic Compartment Prior to Synthesis of Viral Gene Products

The cytoplasmic pattern recognition receptors (PRRs) fall into at least three groups: the Toll-like receptors (TLRs), the RIG-I-like receptors, and the AIM-2-like receptors.^{27,922} At the cell surface, the major PRR relevant to defense against HSV infection is Toll-like receptor 2 (TLR2). Furthermore, current studies indicate that cell surface integrins may also affect TLR2 signaling.¹⁴⁷ In cells lacking $\alpha_3\beta_1$ integrins, HSV enters through a neutral compartment, whereas in cells expressing $\alpha_3\beta_1$ integrins, viral entry is effected through an acidic compartment, likely endocytosis of the virion followed by fusion of the envelope with the endocytic vesicle.³⁷² Targeting of viral entry to lipid rafts could increase viral exposure to TLRs, which are reported to be enriched at lipid rafts after microbial infection.¹⁰⁷⁴ Furthermore, targeting of viral entry through an acidic endosome may increase degradation of the virion and increase the efficiency by which virion components are detected by PRRs in the endosome. The significance of the interaction of virions with the $\alpha_3\beta_1$ integrins in terms of overall defenses of the cell remains a promising area of future investigation.

TLR2 has emerged as a major plasma membrane sentinel of viral interaction on the cell surface.⁹²² HSV infection of cells expressing TLR2 leads to induction of proinflammatory cytokines through the NF- κ B pathway.^{601,602} Sensitization appears to lead to heterodimerization of TLR2-TLR1 through binding of MyD88 and MAL, the activation of NF κ B, and MAP kinases and a whole range of proinflammatory cytokines.⁹²² Murine CMV induces type 1 IFNs via TLR2,⁶² presumably by translocation of TLR2 to endosomes in which a TLR2-TLR1 heterodimer in a complex with MAL and MyD88 activates the Traf3-IRF3/IRF7 signaling pathway; however, there is no evidence of this for HSV. There is evidence that the HSV virion components that trigger TLR2 signaling are surface glycoproteins gB and gH/gC.⁶³⁷ A role for TLR2 in human infections was revealed in a study revealing that two polymorphisms in the *TLR2* gene are associated with increased shedding of HSV-2 and higher recurrent disease rates.¹⁰⁵ In animal studies, TLR2 played a role in protection against HSV-2 disease following intravaginal inoculation but not following intraperitoneal infection.¹⁰⁷⁵ In contrast, TLR2 sensing of HSV-1 infection by the intraperitoneal or corneal routes can lead to increased encephalitis and lethal infection.^{602,996} The ability of different HSV-1 and HSV-2 strains and preparations to induce TLR2 signaling differs,^{997,1181} which may provide some of the basis of virulence of different isolates.

A major endosomal pattern recognition sensor of DNA viruses is TLR9, although TLR7 and a MyD88 dependent pathway are also involved but perhaps to a lesser extent. TLR9 activation requires acidic endosomes, at least in part for viral entry.⁶⁸⁸ In principle, TLR9 recognizes hypomethylated DNA; exposure to HSV DNA in endosomes would occur only if virions were degraded in the endosomes. TLR9 and TLR7 in conjunction with MyD88 induce the phosphorylation of IRF3 and IRF7. Phospho-IRF3 or IRF7 form homo- or heterodimers as part of transcriptional complexes that include NF- κ B and ATF-c-Jun. These transcriptional complexes are powerful acti-

vators of proinflammatory genes that include IFN- α/β , IL-6, IL-12, and TNF- α . The importance of the endosomal TLRs in HSV infection is supported by observations of severe HSV encephalitis in patients with mutations in UNC93B1,¹⁶⁴ which is required for trafficking of TLR7 and TLR9 to the endosome.

This discussion would be remiss without mention of other IFN-inducing cytosolic receptors whose primary function is the detection of DNA. These include DNA-dependent activators of interferon regulatory factors (DAI); leucine-rich repeat flightless-interacting protein 1 (LRRFIP1), which recognizes the AT-rich B form of DNA and GC-rich Z form of double-stranded DNAs; the IFN-inducible protein IFI16; DHX36 and DHX9 shown to bind CpG-A and CpG-B DNA; RNA polymerase III; and inflammasomes activated by DNA viruses that include NLRP3 and AIM2. DAI mediates TBK1-IRF3-dependent induction of IFN in cells exposed to synthetic DNA or HSV.¹¹²³ IFI16 recruits STING to activate the TBK1-IRF3 pathway; it appears to play an important role in innate immunity against HSV.¹¹⁷³ Although IFI16 has been described as a cytosolic DNA sensor,¹¹⁷³ one recent paper reported that IFI16 acts in the nucleus to sense infection by another herpesvirus—Kaposi's sarcoma-associated herpesvirus.⁵⁴² Similarly, in the absence of viral gene expression, HSV can activate IRF3 signaling through nuclear IFI16 in human fibroblasts.⁸³³ DHX36 and DHX9 DEAD box helicases activate IFN via MyD88.⁵⁴⁸ Perhaps the most novel of this group of signaling molecules is RNA polymerase III. The product of this polymerase is uncapped 5' triphosphate RNAs, which induce IFN through activation of RIG-I.^{2,193}

Nuclear Compartment Before Synthesis of Viral Gene Products

Cells recognize as potentially inimical the entry of free DNA into the nucleus, whether it is synthetic and totally devoid of coding sequences, a transfected plasmid, or a viral genome brought into nucleus as a consequence of infection by a virus. In essence, on entry into the nucleus, viral DNA becomes the focus of recruitment of histones,^{207,444,824} histone-modifying enzymes,⁴⁴⁴ repressors of gene expression,⁴⁰⁰ and the assembly of nuclear structures designated PML bodies or ND10s.⁴⁸⁹ The ND10 organizing factor is PML. ND10 bodies are dynamic structures that vary in size and composition. They are present normally in cells but are amplified by IFN, by introduction of DNAs by infection or transfection, and by HDAC inhibitors.⁵²⁸ In infected cells, viral genomes are localized directly adjacent to ND10 structures.⁷²² Some or all of these effects may be related; thus, future experiments to understand the relationship between these different effects are of major importance. The full scope of the modifications imposed on the entering HSV DNA is best described and appreciated from the point of view of the events that lead to its expression, as described earlier.

Activation of Proteolytic and Nucleolytic Enzymes During Entry

In productive entry, endocytosed virus fuses its envelope with the membrane of the endocytic vesicle. The capsid is released into the cytoplasm and is then transported to the nuclear pore, where it releases the viral DNA into the nucleus. Fusion depends on the presence of the viral fusogenic machinery. There is likely always a population of input virions that do not enter, or are incapable of entering, by fusion and could enter and induce signaling through

other pathways. The effects of lack of fusion are shown by the example of gD-negative mutants in which fusion of the envelope with the plasma membrane will not ensue and the virion is degraded. At high multiplicities of infection, massive release of lysosomal enzymes destroys both the virus and the cell.⁷⁷⁴

Summary

The fundamental strategies of the host defenses are three-fold. First, the cytoplasmic organelles and cytosol contain an abundance of pattern recognition sensors capable of detecting virion components prior to *de novo* synthesis of viral gene products. The principal sentinels are PRRs. The signal transduction pathways converge to activate in a cell type-dependent manner the antiviral gene products that include IFN- α/β and proinflammatory cytokines. Second, there are attempts to shut off the synthesis of viral genes both at the point of entry of viral DNA into the virus nucleus and immediately after the onset of synthesis of viral DNA. Third, there is an attempt to commit suicide to preclude the synthesis and dissemination of the virus in the body.

Second Host Defense Perimeter: Activation of Cellular Defense Mechanisms After Onset of Synthesis of Viral Gene Products

Current studies point to three host defense mechanisms that become effective after the onset of accumulation of viral gene products. Of these two, activation of PKR and programmed cell death (apoptosis), if they run their course, commit the infected cell to death.

PKR is activated by IFN and also by double-stranded RNA. In brief, numerous viral transcripts made after the onset of viral DNA synthesis are complementary to each other. Analyses of double-stranded RNA formed by annealing RNA extracted from cells late after infection showed that it had the predicted T_m of and represented transcripts from approximately 50% of the genome.^{493,585} Self-annealing of this RNA could form double-stranded RNA to activate PKR resident in the cytoplasm. Activated autophosphorylated PKR forms dimers that phosphorylate the α subunit of translation elongation factor eIF-2 and I κ B α . The consequences are complete shutoff of protein synthesis by eIF2 α -P and activation of NF- κ B.⁴³⁴

Second, toll-like receptor 3 (TLR3) is an endosomal PRR that is also activated by double-stranded RNA. The importance of TLR3 in host defenses to HSV infection emerged from studies on patients with HSV encephalitis who exhibit mutations in TLR3^{405,1309}; TRIF, one of its adaptor molecules,⁹⁹³ or TRAF3, which interacts with TRIF.⁸⁶⁵ TLR3 is presumably sensing the viral double-stranded RNA molecules described earlier; however, it remains to be defined how these molecules are sensed by TLR3 in the endosome.

Cell death as a preemptive response to infection is triggered by at least three events. First, as described previously, high multiplicity infection with a virus that is unable to enter the cell by fusion of the envelope with the membrane of the endocytic vesicle triggers a massive influx of lysosomal enzymes, resulting in the lysis of the virus and the killing of the cell.⁷⁷⁴ Second, activation of PKR may lead to cessation of all protein synthesis. Third, infection with α gene mutants (e.g., $\Delta\alpha 4$, $\Delta\alpha 27$) that are unable to express post- α or - β genes may trigger apoptosis. Cell death results from activation of caspases.⁷⁷⁴ Overexpression of ICP0 can cause apoptosis; however, the full range of

viral products that trigger apoptosis under normal infections is not known.

Finally, it would be remiss not to mention activation of autophagy. In principle, shortage of nutrients could force the cell to resort to proteolysis of its own proteins to meet its current shortage of amino acids. Autophagy typically initiates with the appearance of cup-shaped membrane structures in the cytoplasm that ultimately evolve into an autophagosome through the intervention of lipid kinase Vps34. This enzyme phosphorylates lipids in association with an array of Atg proteins that include Beclin (Atg6) and LC3 (Atg8).^{14,1053} Protein degradation is the consequence of an influx of lysosomal enzymes into the autophagosome. The role of autophagosomes as a host defense mechanism is at this stage speculative, although evidence is mounting. Autophagosomes could hypothetically furnish viral components to class II antigen presentation pathways or expose viral DNA and RNA to PRRs.

Strategy of Viral Conquest of the Host Cell

The strategy employed by the virus is to preempt any response on the part of the cell to the presence of the virus or its components. Some preemptive strikes are carried out by virion components brought into the cell during infection or made after infection. A key component of the strategy is to block any potential response by multiple mechanisms expressed by different gene products. On the basis of the number of functions directed to suppress a specific host response, the synthesis of IFN and of IFN-dependent host gene products emerge as the major targets of the viral strategy of conquest. It is convenient to consider the preemptive acts in terms of their objective.

Shutoff of Host Responses Prior to Onset of Viral Expression of Viral Gene Products

There are two fundamental mechanisms by which the virus preempts the host responses to infection prior to *de novo* synthesis of viral gene products: suppression of degradation of virions by lysosomal enzymes and degradation of cellular stress response mRNAs.

SUPPRESSION OF DEGRADATION OF VIRIONS BY LYOSOMAL ENZYMES

As noted previously, virions lacking gD are endocytosed and degraded by an influx of lysosomal enzymes. The escape of wild-type virions from degradation is attributed to the presence of gD. This conclusion is based on the observation that apoptosis does not take place in cells transfected with a plasmid encoding gD prior to exposure of the cells to a Δ gD mutant virus. gD appears to block fusion of lysosomes with the endocytic vesicles.¹³¹⁶ This argues that normal virions unable to fuse could also undergo degradation and induce TLR signaling and apoptosis.

DEGRADATION OF CELLULAR STRESS RESPONSE MESSENGER RNAs

Within a very brief interval after exposure to HSV, the cell responds by activation of NF- κ B and the synthesis of a wide array of stress response mRNAs with the ultimate objective to block the synthesis of viral gene products. After a brief burst of activation of NF- κ B by gD binding to HVEM⁷³⁷ and the U_L37 tegument protein binding to TRAF6,⁶⁶⁴ HSV reduces this

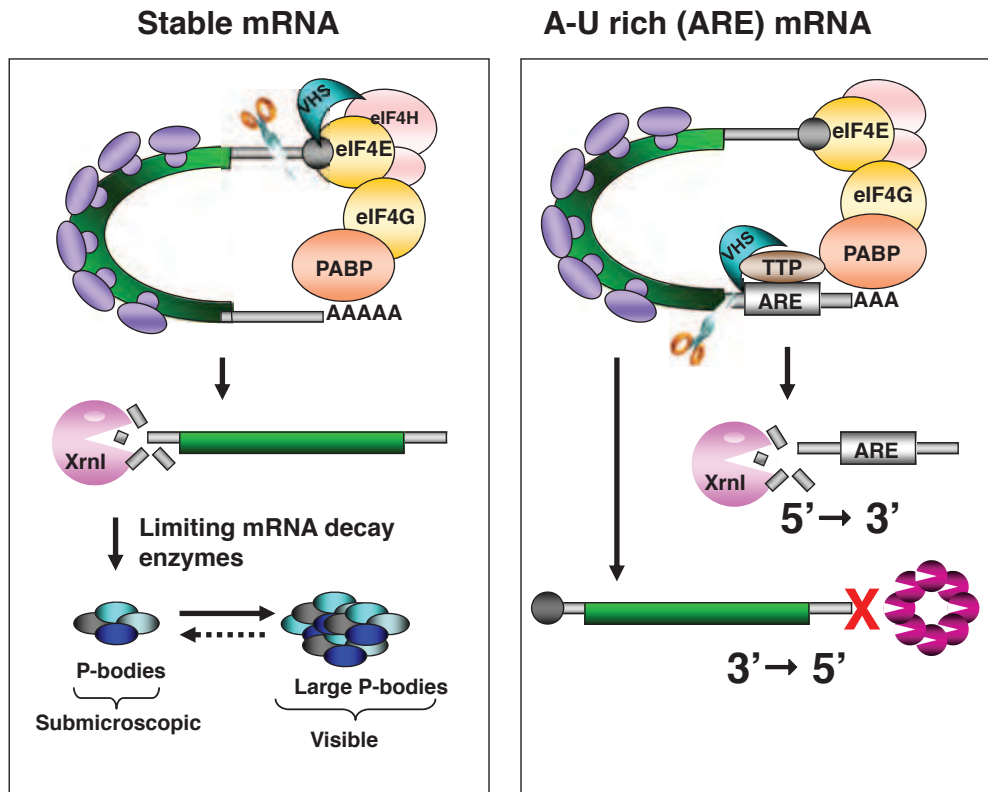

FIGURE 60.12. Model of messenger RNA (mRNA) degradation by VHS-RNase. **Left:** Degradation of Stable mRNAs. VHS binds to polyribosome-associated translation factors and cleaves the mRNA in the 3' untranslated region, leading to 3' to 5' degradation. **Right:** Degradation of A-U-rich (ARE) mRNAs. VHS binds to polyribosome-associated tristetraprolin (TTP), leading to cleavage at or near the ARE elements.

response by degradation of the stress response mRNAs by the VHS RNase, a tegument protein encoded by the *UL41* gene.³¹⁷

VHS is an endoribonuclease with the specificity of RNase A.¹¹¹⁶ It has been shown to bind to both cap- and poly(A)-binding proteins. A model of its activity is illustrated in Figure 60.12. Briefly, VHS can degrade mRNAs in polyribosomes, implying that it binds to mRNAs in the course of translation.¹¹²⁰ VHS rapidly degrades stable mRNAs exemplified by GAPDH or actin mRNAs by binding to cap structures and cleaving the mRNAs 3' to the cap.⁸³⁶ The mRNAs are then degraded 5' to 3'. The high amounts of RNAs targeted for degradation precipitate an increase in size and number of processing bodies.¹¹²⁰ The process of degradation of A-U-rich (ARE) mRNAs is different. ARE RNAs contain stretches of A-U-rich sequences in the 3' UTRs and in uninfected cells have characteristically a short half-life. The A-U-rich elements bind to members of the HuR protein family and to tristetraprolin, which sequesters the ARE mRNAs for degradation. Tristetraprolin is induced in infected cells, and it has been shown to bind VHS.³¹⁶ In wild-type virus-infected cells, ARE mRNAs are cleaved at or near the A-U-rich elements, presumably by VHS bound to tristetraprolin.¹¹¹⁵ The portion of the mRNA 5' to the cleavage site tends to linger in infected cells for many hours,³¹⁷ presumably because of a dearth of enzymes that degrade mRNA from 3' to 5'.

Whereas the VHS RNase functions efficiently in the absence of viral proteins made after infection, in practice the

pre- and postviral protein synthesis activities of VHS cannot be readily differentiated. In synchronously infected cells, VHS is active for at least 5 to 7 hours. To be ectopically expressed in transfected cells, the RNase activity of VHS must be neutralized by concomitant production of VP22 (*UL49*) and V16 (*UL48*).¹¹¹⁷ Viral replication does not ensue in the absence of a neutralizing partner. For example, replication-competent Δ VP22 mutants exhibit mutations in the VHS genes.¹⁰²²

VHS is highly effective in degrading stable mRNAs. A key unresolved question is the mechanism by which HSV transcripts escape total degradation. In transfected cells or *in vitro*, VHS is highly effective in degrading viral mRNAs. The prevailing doctrine is that so much viral mRNA is produced that a sufficient amount escapes degradation. This view is difficult to reconcile with the evidence that in Δ *UL41* mutant virus-infected cells, the transition from α to β and γ protein synthesis is delayed. The hypothesis that the RNase activity is selective or defined by interacting partners is sustained by the observation that some mRNAs appear to be stable even while other mRNAs synthesized concurrently are degraded. ICP27 is one potential partner of VHS that is identified on the basis of its interactions with VHS and potential co-localization in mRNA undergoing translation.^{530,1118}

Other Tegument Proteins

The dominant role of VHS in shaping the response of the infected cells has overshadowed investigation of the role of

other tegument proteins in blocking host responses to infection. The functions of known tegument proteins are shown in the Herpes Simplex Virus Gene Functions List section. A smaller set comprising three proteins is considered next.

VP22 has been reported to be secreted and taken up by adjacent cells. The protein also binds and packages mRNA, both viral and cellular, in virions. The viral mRNAs packaged in virions, although highly diverse, are not random. The RNAs transported by VP22 are expressed in recipient cells; however, the contributions of these mRNAs to the preparation of the infected cell to reproduce the infecting virus is unknown.¹⁰²³

The *U_L11* gene product is an abundant tegument protein. It binds both single- and double-stranded RNA.⁹⁶² It is known to block PKR late in infection and to be associated with polyribosomes at early times.^{165,964} Its role, if any, in blocking host responses to infection at early times is not readily apparent because deletion of the gene has a negligible effect on the pathogenicity of the virus.

ICP0 is defined as a tegument protein by its presence in virions.¹²⁹³ Its function as a tegument protein is not readily apparent and remains to be elucidated.

Shutoff of Host Responses After Onset of Synthesis of Viral Gene Products

The fundamental mechanisms by which the virus shuts off the host after the onset of synthesis of viral gene products are as follows: (a) inhibition of host gene transcription, (b) continuing degradation of cellular mRNAs by VHS described earlier, (c) suppression of silencing of viral DNA by cellular proteins, (d) degradation of specific cellular proteins, (e) disruption of splicing of cellular mRNA accompanied by enhancement of cytoplasmic transport of unspliced mRNA, (f) induced disappearance of short-lived cellular proteins owing to degradation of the mRNAs, (g) inhibition of apoptosis and of autophagy by viral gene products, (h) inhibition of presentation of the antigenic peptides to the adaptive immune system, and (i) inhibition of cytotoxic effects of the cellular immune system.

INHIBITION OF HOST GENE TRANSCRIPTION

HSV infection reduces host gene transcription as measured by nuclear runoff transcription assays.¹⁰⁸¹ However, the quantitative effects of HSV infection and the viral gene products required vary with the cellular gene being studied, although ICP27 was required for inhibition of many of the cellular genes studied.¹⁰⁸¹

SUPPRESSION OF SPLICING OF CELLULAR PRE-MESSENGER RNAs

ICP27 plays a key role in blocking host responses to infection.⁹⁹⁵ In addition to inhibiting host gene transcription, ICP27 performs two key functions. First, early in infection, it interacts with SR proteins, which are components of the pre-mRNA splicing machinery, and recruits the SR protein kinase 1 into the nucleus where it phosphorylates the SR proteins so that spliceosome assembly is inhibited.^{652,1019} This function is executed for several hours and ceases on onset of expression of late viral genes. The net effect is that most cellular pre-mRNAs are not processed correctly and are not translated. A second function of ICP27 is to chaperone viral mRNAs virtually from the time of synthesis to their translation in the cytoplasm

inasmuch as ICP27 has been pulled down in complexes with RNA polymerase II^{245,1314}; the ICP4 transactivator⁸³⁸; CLOCK HAT⁵³⁰; RNA-binding proteins RNA helicase A and hnRNP-F¹³¹⁵; RNA export protein Aly/REF¹⁸⁴; and translation factors including PABP, eukaryotic initiation factor 3 (eIF3), and eukaryotic initiation factor 4G (eIF4G).³³⁹ Still unresolved is the significance of the interaction of VHS with ICP27.¹¹¹⁸ It is conceivable but as yet unproven that ICP27 binds to VHS to block the degradation of the mRNA that it chaperones.

SUPPRESSION OF SILENCING OF VIRAL DNA BY CELLULAR PROTEINS

Immediately upon entry into cells, viral DNA becomes the focus of assembly of histones, histone and DNA modifying enzymes, and repressors. HSV gene products combat this host cell silencing. In addition, ND10 nuclear bodies assemble near the DNA. Viral gene expression depends on remodeling of the viral chromatin. Thus, at least as a preemptive move, HSV degrades components of ND10. These topics have been discussed in detail in the Viral Gene Expression section and in recent reviews.^{560a,947}

Degradation of Cellular Proteins

A key event early in infection associated with the localization of ICP0 at ND10 bodies is the degradation of two key components of ND10: PML and Sp100. In this instance, ICP0 acts as an E3 ubiquitin ligase.^{116,410} It recruits the UbcH5A ubiquitin conjugating enzyme to degrade both proteins.⁴⁰³ The E3 activity maps to the RING domain encoded by exon 2 of ICP0. As a consequence, the components of ND10 bodies become dispersed and are replaced by viral and cellular proteins that ultimately form the viral replication compartments.¹¹⁷⁵ As described earlier, ICP0 promotes, either directly or indirectly, the degradation or reduction in the levels of several cellular proteins. One key function of ICP0 is to block host intrinsic immunity factors via degradation of important cellular proteins such as PML and Sp100. A second key function of ICP0 is to block innate immune responses through reduction of the levels of important signaling molecules. For example, ICP0 causes reduced induction of IFN- β by Sendai virus co-infection, potentially by sequestering IRF3 in the nucleus away from the IFN promoter and by accelerating its degradation.^{742,743} Nuclear ICP0 expressed by HSV-1 *d106* virus in the absence of expression of other viral proteins can block IFN- β induction by Sendai virus or IFN- β induction by HSV infection,⁷⁴³ thus this seems to be a direct effect of ICP0 and not downstream effects of later events in the infection cycle. In human fibroblasts, IFI16 is required for IFN- β and IFN-stimulated gene responses to HSV infection, and HSV ICP0 causes intranuclear relocalization and degradation of IFI16.⁸³³

To counter the production of proinflammatory cytokines, ICP0 inhibits the TLR2 signaling pathway and, at least under certain circumstances, causes a reduction in levels of the adaptor molecules in this signaling pathway.¹¹⁸³ Although the expectation would be that ICP0 causes this effect during its cytoplasmic phase late in infection, a virus expressing a mutant ICP0 that remains nuclear can still inhibit TLR2 signaling.¹¹⁸³ This would seem to be an example of an indirect effect exerted by ICP0. There is also evidence that cytoplasmic ICP0 can block activation of IRF3⁸³⁷ and that cytoplasmic ICP0 can block TLR signaling via promotion of the nuclear export of

the USP7 deubiquitinase,²⁵¹ although the latter results have not been corroborated.

Overcoming the Shutoff of Protein Synthesis by Activated Protein Kinase R

Virtually every virus that synthesizes complementary RNA must find a way to block the activation or function of PKR. HSV encodes two proteins that thwart the function of PKR.

As the name indicates, ICP34.5, the product of the γ_1 34.5 gene, is a late protein whose accumulation is augmented by the onset of viral DNA synthesis. ICP34.5 has at least two key functions. First, the terminal domain of ICP34.5 contains the motif of a phosphatase accessory factor: It binds protein phosphatase 1a and redirects it to dephosphorylate eIF-2 α -P, thereby enabling uninterrupted protein synthesis.⁴³⁴ Curiously, ICP35.5 does not block activation of NF- κ B. One explanation is that HSV requires one or more NF- κ B-dependent proteins inasmuch as HSV replicates to a lower level in NF- κ B-minus cells.^{20,853} The second known function of ICP34.5 maps in the N-terminal domain of the protein. It interacts with Beclin/Agt6 and blocks autophagosome formation.^{14,1053}

U_s11 blocks activation of PKR by binding to it prior to its activation.¹⁶⁵ U_s11 is a late protein, and its function as an inhibitor of PKR is most apparent when the gene is driven by an α rather than a γ_2 promoter.⁴³²

Blocking Apoptosis

HSV expresses several gene products that preclude the self-destruction of the infected cell. These include, in addition to gD and gJ noted previously, the U_s3 protein kinase.⁷⁷⁴ Cells infected with mutants unable to express ICP4, ICP27, or ribonucleotide reductase undergo apoptosis in a cell-type-dependent fashion. Implicit in these findings is that (a) the cell senses the presence of noxious viral gene products that trigger apoptosis, and (b) a gene function that is expressed later in infection and whose expression requires the missing gene functions blocks apoptosis. Consistent with this view, wild-type virus blocks apoptosis in cells induced by high temperatures or by sorbitol, a potent osmotic shock inducer. Indeed, ectopic expression of U_s3 protein kinase blocks apoptosis induced by sorbitol, or overexpression of caspase 3 or the BAD proapoptotic inducer. To block apoptosis, the U_s3 protein kinase requires the protein kinase activity mapping in its C-terminal domain and a sequence mapping close to the N-terminus. Recent studies led to the identification of a protein—the cellular programmed cell death protein 4 (PDCD4)—that binds to the U_s3 protein kinase. Depletion of this protein precludes apoptosis following infection with Δ ICP4 mutant.¹²¹⁵ Nevertheless, the U_s3 protein kinase is unlikely to express the only antiapoptotic function of HSV inasmuch as Δ U_s3 mutants do not induce apoptosis.

Inhibition of Adaptive Immunity

In addition to their effects on innate immunity, HSV gene products also inhibit adaptive immune responses in several ways.

1. *ICP47 and MHC class I presentation.* The small ICP47 protein blocks presentation of MHC class I peptides by binding in the pore of the transporter of antigen presentation (TAP) and blocking transport of peptides from the cytoplasm into the lumen of the ER for loading on MHC class I molecules.¹³⁰² The net result of this effect would be to reduce or totally block CD8⁺ T-cell induction. The significance of this viral gene product in viral infection has not been determined experimentally because ICP47 does not bind to TAP of small animals commonly used for HSV infection models, but only to TAP of larger domestic animals, nonhuman primates, and humans.⁴⁴⁶ This function of ICP47 might be especially relevant in neuronal cells that express low levels of TAP and MHC class I molecules.
2. *gE and Fc receptor activity.* HSV gE and gI form an Fc receptor that binds the Fc region of IgG and blocks antibody neutralization of virions, antibody-dependent cytotoxicity, and phagocytosis.^{296,345,1185}
3. *gC and complement.* HSV-1 gC binds complement component C3b and inhibits the interaction of the next components of the pathway, C5 and properdin, thereby preventing activation of the classical and alternative pathways.^{353,582}
4. *HSV and T-cell receptor signaling.* HSV-infected cells cause a loss of T-cell functions in co-incubated T cells, including cytotoxicity, and production of cytokines.⁵⁰⁰ The functional defect is owing to a failure of the T-cell receptor signal to propagate beyond the adaptor molecule, the linker for activation of T cells, owing to the lack of recruitment of PLC- γ 1, Grb2, and GADS to the adaptor complex. The viral genes involved in this block have not been identified. For this effect, HSV has to directly infect the T cells; however, HSV can spread from other cell types to T cells via virological synapses.⁴¹
5. *HSV and cytotoxic T-cell (CTL) function.* HSV-1 infection renders cells resistant to CTL-induced apoptosis.⁵⁰³ HSV-1 infection blocks apoptosis induced by anti-Fas antibody or UV irradiation, whereas HSV-2 clinical isolates do not block these effects.⁵⁰² Deletion of the U_s3 gene reduced inhibition of UV-induced apoptosis and partially inhibited Fas antibody-induced apoptosis, whereas deletion of the U_s5 gene had the opposite effect.⁵⁰² HSV-1 gJ (U_s5) inhibits caspase activation and apoptosis induced by granzyme B or Fas.⁵⁰¹ In contrast, U_s3 may block TCR signaling.¹⁰⁵⁷ These effects show at least part of the reasons why the host immune system cannot completely control HSV infection prior to spread to neuronal cells for establishment of latent infection.
6. *HSV and CD4⁺ T-cell function.* HSV infection of B-lymphoblastoid cells reduces their ability to induce CD4⁺ T-cell clone proliferation and cytokine expression.⁶³ The effect was not associated with down-regulation of MHC class II molecules or co-stimulatory molecules. HSV-1 U_s1 expression is necessary and sufficient for this effect and also rendered cells less susceptible to CD4⁺ T-cell-mediated lysis.⁶³ These effects provide further means by which HSV evades host immune responses.
7. *gB, U_s3, and NKT cells.* HSV-1 infection rapidly down-regulates CD1d expression and inhibits NK T-cell function. HSV-1 does this primarily by suppressing CD1d recycling from the ER to the cell surface.¹³⁰⁴ A recent study identified gB and U_s3 as two viral factors functioning in suppressing CD1d antigen presentation by retaining CD1d in the *trans*-Golgi network.⁹¹⁹

Interferon: Herpes Simplex Virus Enemy Number 1

The main objective of the previous sections was to relate suppression of cellular responses to infection by specific viral gene functions. Shutting down IFN-dependent host responses to infection readily emerges as the main objective of the virus on the basis of the number of viral functions aimed at shutting down the cell. Degradation of mRNAs, inhibition of cellular protein synthesis by inhibiting splicing of pre-mRNAs, degradation of PML and IRF3 signaling molecules, and dispersal of ND10 bodies and alteration of functions of cellular proteins by the viral protein kinases are prime examples of the scope and range of functions deployed to suppress the IFN response.^{182,742}

LATENT INFECTION

The ability of HSV to establish a lifelong latent infection in its human host is one of the most intellectually challenging aspects of HSV biology. Owing to space constraints, we are not able to discuss and cite all of the extensive studies in this area; nonetheless, there are several recent, more detailed reviews.^{102,810,867,947} The available data on HSV latent infection support the following sequence of events (Fig. 60.13). Following spread in the tissue at the primary site of infection, the virus enters sensory neurons by fusion at the axonal termini, and the nucleocapsid is carried by retrograde axonal transport to the nucleus in the cell body of the neuron (see Fig. 60.13A). Viral DNA persists in the nucleus in a circular episomal form associated with nucleosomes (see Fig. 60.13B). Lytic gene expression is repressed; however, LAT is expressed at high abundance, which yields several RNA species upon processing and splicing. No replicating virus can be detected in the sensory ganglia during latent infection. In a fraction of neurons harboring latent HSV, the virus is periodically reactivated (see Fig. 60.13C). Infectious virus is carried by anterograde axonal transport to peripheral tissues, usually to cells at or near the site of initial infection. Depending on several factors, including the host immune status, the reactivation may be asymptomatic or lead to a recurrent lesion, which may vary considerably in severity from punctate lesions that are invisible to the naked eye to severe, debilitating lesions in immunosuppressed individuals.

The ability of sensitive PCR tests to measure HSV DNA in genital secretions has led to the detection of frequent viral DNA shedding in the genital tract of both asymptomatic and symptomatic individuals.¹²⁰⁷ This frequent shedding has led to questions about whether HSV latent infection is actually a low level chronic infection producing constant shedding of virus rather than a true latent infection.¹⁰⁰⁶ However, the amount of virus shed in many of these individuals is very low, and this could represent viral DNA molecules that are shed in epithelial cells rather than virions. The number of DNA molecules detected, even if it does represent recent release, would only require a limited number of neurons to be reactivating at any one time. Therefore, it seems likely that the bulk of the infected neurons are undergoing a latent infection, as described previously, and only a small number are reactivating at most times. Nevertheless, the possibility of low-level chronic infection, especially with HSV-2, remains.

Latent infection was first detected experimentally by co-cultivation of sensory ganglia tissue with permissive cells and

detection of cytopathic effect owing to reactivated virus.¹⁰⁹⁹ Infectious virus was not detected in homogenized ganglia; therefore, the virus was latent in the tissue at the time of explant. This led to the original definition of latency—virus must be able to reactivate from the latent state under appropriate experimental conditions. Operationally, this meant that virus could be detected after incubation of intact ganglionic tissue with suitable susceptible cells, but not by inoculation of the susceptible cells with homogenized ganglia. The definition of latency was later extended to include viruses that can be detected in sensory ganglia several weeks after infection by *in situ* hybridization with probes for the LATs or by assays to detect viral DNA in ganglia.^{212,535,632,634} At the present time, the only technique for proving that a virus is incapable of establishing latent infections is the inability to detect viral DNA by polymerase chain reaction (PCR) assays of DNA extracted from whole ganglia. This extension of the definition of latent infection enables an

FIGURE 60.13. Stages of herpes simplex virus (HSV) infection of the host. A: HSV is introduced onto a mucosal surface or a break in the skin, and it replicates productively in epithelial cells at the site of inoculation and spreads through the tissue. Virus enters sensory neuron axons and is transported to the cell body in a ganglion. **B:** HSV establishes a latent infection in the neuronal cell nucleus. Viral DNA is circular and assembled in chromatin. **C:** Upon neuronal damage or activation, the virus reactivates and undergoes at least a limited productive cycle. Capsids are transported by anterograde transport to the axonal termini, and virions are released. Reactivated virus causes a recurrent infection of the mucosal tissue, causing the shedding of virus. (Copyright Lynne Chang and David Knipe.)

assessment of the roles of specific genes in the establishment and maintenance of latency, separate from their roles in reactivation. The downside of the revised definition is that it equates the presence of viral DNA with a bona fide latent state defined biologically as at least capable of reactivation. Because viral DNA has been detected in the CNS and even at peripheral sites, the redefinition arguably extends the sites of viral latency beyond currently proven sites.

The burning question of HSV latency remains: How can HSV undergo a productive infection in epithelial and other nonneuronal cells but undergo a latent infection in sensory neurons? Numerous corollary questions derive from this: Are there intrinsic nonpermissive features of neurons that allow the latent infection? Does the virus play an active or passive role in the latent infection? Does the host immune response control the latent infection or just the lytic infection? Some of these questions are addressed next.

Herpes Simplex Virus Latency in Experimental Systems

Latent infection by HSV has been achieved in cell culture systems only under special conditions that usually involve HSV inhibitors.^{32,146,1258} As a result, the most meaningful models have been animal infection systems. The most useful animal model systems are mice and rabbits for HSV-1 infection and guinea pigs for genital infection by HSV-2. In all three species, inoculation of wild-type virus results in viral replication at the peripheral site and retrograde transport of virus to the nucleus of dorsal root neuron, followed ultimately by establishment of latency. In all three systems, a fraction of sensory neurons replicate the virus following entry into the neuron.

There are several key differences in the animal models. In rabbits, both HSV-1 and HSV-2 reactivate spontaneously. The rabbit eye model is particularly useful for studies of spontaneous reactivation because the virus is readily detected in lacrimal secretions. The guinea pig is a useful model of HSV-2 genital infections. The virus reactivates spontaneously, causing lesions containing small amounts of virus, although the acute and recurrent phases are somewhat artificially defined. The virtues of the mouse model are twofold. First, highly inbred strains differ with respect to their susceptibility to infection, and knockout mice have been particularly useful in studies of immune responses to infection.⁶⁷⁸ Second, detection of spontaneous reactivation of virus resulting in the appearance of infectious virus either in ganglia or at peripheral sites is very rare in mice. Latent virus in mice can be induced to reactivate, leading to appearance of virus in sensory ganglia or at peripheral sites by peripheral tissue trauma, UV light exposure, hyperthermia, or administration of drugs that stimulate prostaglandin synthesis. Reactivation has been studied in murine systems following explant of ganglia in culture¹⁰⁹⁸ or *in vivo* owing to tissue trauma,⁴⁴⁸ transient hyperthermia,¹⁰⁰² UV irradiation,⁶²⁴ or epinephrine iontophoresis in the eye.¹²⁶³

Viral DNA During Latent Infection

In latently infected neurons, viral genomes acquire the characteristics of endless or circular DNA^{347,741,943,944} assembled in nucleosomal chromatin.²⁷² Histone modifications, particularly methylation and acetylation, play an important role in defining the type of regulation imposed on eukaryotic genes by nucleo-

somal chromatin, with particular modifications resulting in chromatin-mediated gene activation (active or euchromatin) or repression (inactive or heterochromatin).⁴⁹⁹ During latent infection, the LAT promoter and 5' exon are associated with acetylated histones or active chromatin, whereas lytic gene promoters are not associated with acetylated histone H3.⁵⁹⁷ In contrast, viral lytic gene promoters are associated with heterochromatin forms of histones during latent infection.¹²¹⁴ The heterochromatin modifications include histone H3 lysine 27 trimethylation,^{206,604} and histone H3 lysine 9 trimethylation²⁰⁶ but little of the constitutive heterochromatin marker H3K20 me3.²⁰⁶ HSV DNA is not methylated during latent infection.^{292,598} Current models for maintenance of HSV latent infection include the silencing of all viral lytic genes except for the *LAT* gene by heterochromatin and microRNAs.

Viral RNAs Expressed During Latency: Herpes Simplex Virus Latency-associated Transcripts and microRNAs

During latent infection, the only viral gene products expressed at abundant levels are the LATs, first detected in latently infected murine ganglia,¹¹⁰¹ and microRNAs, first detected in latently infected human¹¹²⁶ and murine ganglia.¹¹⁶⁸ The LATs were subsequently found in latently infected rabbit⁹⁴⁵ and human^{590,1100} ganglia. The *LAT* transcriptional unit (Fig. 60.14) yields several RNA species by splicing, and these are collectively referred to as LATs. The LATs constitute a family of transcripts mapping to the inverted repeats flanking the U_L sequence. The full-length 8.3- to 9-kb transcript accumulates at low levels in latently infected neurons, whereas 2- and 1.5-kb introns processed from a full-length transcript are abundant and accumulate in the nucleus.¹¹⁹⁹ These introns are highly stable as a result of unusual lariat structures.³²⁹ The 2-kb LAT is the major species detected in neuronal nuclei by *in situ* hybridization¹¹⁰¹ (Fig. 60.15). LATs are expressed from a neuron-specific promoter/enhancer.¹³²⁶ Although the 2-kb LAT is detected in productively infected cells at late times postinfection, this is likely to be the result of splicing of read-through transcripts that are common at late times postinfection^{383,493} or another promoter and not transcription from the true LAT promoter.¹⁸⁷ Despite reports of proteins encoded by LATs,^{283,1139} most workers in the field have found no evidence for expression of proteins by the LATs.²⁹³

Organization of the *LAT* Gene

The primary LAT initiates at bp 118,802 on the HSV-1 genome based on RNase mapping of the primary transcript²⁷⁴ or at 118,803 using *in vitro* transcription¹⁰⁶⁸ and extends for 8.3 to 9 kbp, possibly reading through the L-S junction and overlapping the *ICP4* gene at its 3' end (see Fig. 60.14). The 5' exon extends from bp 118,803 to 119,465, and the major intron extends from bp 119,465 to 121,417. The *LAT* promoter is from bp 118,003 to 118,878. A second promoter, sometimes referred to as the LAP2 promoter, has been identified in transient assays only¹⁸⁷ and extends from bp 118,867 to 119,461. An enhancer allowing long-term expression of LAT (long-term enhancer element, or LTE) extends from bp 118,077 to 119,461 and is located downstream from the *LAT* gene transcriptional start site.^{87,668,669}

There are several other transcripts near or overlapping the *LAT* gene or its promoter that could conceivably play a

FIGURE 60.14. Map of the *LAT* transcriptional unit. **A:** HSV-1 genome in the prototype orientation; U_L and U_S denote the unique sequences of the long (L) and short (S) components of the genome, respectively. Boxes denote repeated sequences. **B:** Expanded view of the L–S junction of the HSV-1 genome showing the regulatory elements, including the *LAT* promoter (LAP),^{280,1325} long-term enhancer element (LTE),^{86,668} CTCF (CCCTC-binding factor) motifs and putative insulator sites labeled as CTRL1, CTRL2, CTRL3, CTa' and CTRS1, CTRS2, and CTRS3.¹⁸ **C:** LATs including the ≥8.3-kb *LAT* primary transcript; 2-kb and 1.5-kb *LAT* stable introns. **D:** MicroRNAs encoded by the *LAT* region: miR-H1, miR-H2, miR-H7, miR-H3, miR-H5 and miR-H4, miR-H6, and miR-H8. **E:** Locations and orientations of transcripts including infected cell protein (ICP) 0, ICP4, and γ 34.5^{194,195}, open reading frame (ORF) P⁶¹³, L/STs¹²⁹⁸, upstream of *LAT* (UOL)⁷⁹⁰, 0.7-kb *LAT* (only in strain 17 and McKrae, not KOS) antisense to *LAT*s AL-*LAT*, AL-2, and AL-3^{490,869}; small RNAs⁸⁶³; and partially characterized transcripts α X and β X.^{108,109} **F:** *LAT* mutations in the KOS strain: KOS Δ Pst is an *LAT* promoter deletion between two PstI sites, and KdILAT is a 1.8-kb deletion of PstI–HpaI that eliminates the *LAT* promoter and 1.6 kb from the 5' end of the *LAT*.

role in *LAT* function or contribute to the phenotypes of *LAT* gene mutant viruses (see Fig. 60.14). First, for example, a 0.7-kb transcript encoded on the same DNA strand as *LAT* but upstream of *LAT* is expressed by HSV-1 strains 17 and McKrae but not by strains KOS and F.¹³²¹ Second, transcripts that are complementary to the *ICP4* gene transcripts, called *anti-4 transcripts*, were detected by reverse transcriptase (RT)-PCR.¹⁸⁵ The *anti-4* transcript(s) may be expressed from a new transcriptional unit downstream of the primary *LAT* transcriptional unit or expressed as a read-through transcript from *LAT*; however, in any case, *anti-4* transcription is promoted by *LAT* expression.¹⁸⁵ Third, a transcript that is antisense to the 5' end of *LAT* has been identified as encoded by HSV-1 strain McKrae and reported to express a protein in infected rabbits.⁸⁶⁹

Two ORFs encoded with the domain transcribed by the 8.3-kb *LAT* are ORF P and ORF O.^{613,614} Because their mRNAs are tightly down-regulated by ICP4, these were candidates for gene products that might affect latency. However, inactivation of the ORFs had no effect on the ability of the virus to replicate

in experimental animal systems, and only a slight effect on the amount of virus recovered from latently infected ganglia.⁹¹⁵

The literature on LATs is enormous but does lend itself to a brief summation. Thus, some studies reported that viruses deleted in various domains of *LAT* establish latency at normal levels,^{495,631,1096} whereas others reported that the number of neurons harboring *LAT*-negative viruses were decreased by three- to fivefold.^{1002,1146} It is conceivable that assaying numbers of latently infected cells is a more quantitative assay of latent infection than measurement of total viral DNA molecules. Still others reported reduced explant reactivation of virus from ganglia latently infected with *LAT*-negative mutant viruses,⁶³¹ although in some cases *LAT*-negative mutant viruses show reduced replicative ability.¹⁰⁰ The region of the LATs associated with decreased reactivation has been mapped to a 348-bp sequence in the 5' end of *LAT*.^{103,447}

Several studies have shown effects of *LAT* on viral gene expression or replication. First, *LAT*-negative mutant viruses show elevated productive viral gene expression in sensory neurons during acute infection³⁶⁰ and during latent infection.¹⁸⁶

FIGURE 60.15. Detection of herpes simplex virus stable latency-associated transcript (LAT) RNA in latently infected murine trigeminal ganglion neurons by fluorescence *in situ* hybridization (FISH). Mice were infected with HSV-1 following corneal scarification. At 30 days postinfection, the mice were sacrificed, and trigeminal ganglia were frozen and sectioned. The sections were hybridized with a labeled DNA probe detecting the LAT RNA (shown as *red*). Neurons were stained with antibodies detecting neurofilament proteins (*green*). (Copyright Lynne Chang and David Knipe.)

Consistent with this, expression of LAT has been shown to reduce viral gene expression and replication in cultured cells.⁷⁰⁰ LAT-negative mutant viruses have been shown to give higher pathology in trigeminal tissue,⁶³¹ to cause neuronal death,¹¹⁴³ and to cause higher mortality in infected mice.^{1143,1214} This silencing effect of LAT has been attributed in part to the assembly of heterochromatin on viral lytic gene promoters.¹²¹⁴ Recent studies using viruses that mark infected cells⁹⁰⁰ have shown that fewer neurons survive infection with an LAT-negative mutant virus.³⁰⁹ A further function attributed to LATs is that they protect neurons from apoptosis. Thus, a virus deleted for LAT was reported to induce apoptosis in rabbit trigeminal ganglia at slightly higher levels than the wild-type virus.⁸⁶⁶ The effect of LAT on apoptosis in mice is less clear because some did not observe the same effect in mice,^{866,1144,1145} whereas others have observed this effect of LAT in mice.¹² LAT expressed from a plasmid vector can protect cells from cell death induced by etoposide, ceramide, or other agents.^{12,487,870} Although the original hypothesis was that the LATs protected sensory neurons from apoptosis during acute infection,⁸⁷⁰ others have argued that the effect of LATs on establishment of latent infection may be minimal and that it is more likely that the LATs play a role in blocking apoptosis during reactivation.¹⁰¹ LATs can also protect neuronal-derived cells from CD8⁺ T-cell killing.⁵⁰⁵ Thus, a common theme of LAT studies has been that LATs protect neurons from death,¹⁰¹ either by reducing viral gene expression, by protecting against apoptosis, or by other mechanisms. Nevertheless, a few studies have shown that LAT increases lytic gene expression³⁷⁸ and reduces heterochromatin.⁶⁰⁴

LAT expression has also been reported to promote CD8⁺ T-cell exhaustion in trigeminal ganglia through increased expression of PD-1 and Tim-3.^{15,189} LAT directly or indirectly up-regulates both PD-L1 and MHC class I on mouse neuroblastoma cells. Further studies are needed to define the relationships between this new function and the other LAT functions.

microRNAs

A large number of microRNAs have now been shown to be expressed during latent infection. In latently infected murine trigeminal ganglia, these include miR-H1,^{240,589} miR-H2, miR-H3, miR-H4, miR-H5, and miR-H6,¹¹⁶⁸ as well as miR-H7, miR-H8, miR-H17, and miR-H18.⁵²¹ In guinea pig ganglia latently infected with HSV-2, microRNAs shown to be expressed are miR-I (miR-H3), miR-II (miR-H4), and miR-III (miR-H2). In human trigeminal ganglia, these include miR-H1-8¹¹⁶⁹; in human sacral ganglia, they include miR-H3, 4, 7, 9, and 10.^{1126,1170} Many of these microRNAs are likely to be processed from the primary LAT because their expression depends on the LAT promoter.^{589,1127} Furthermore, miR-H6 expression is reduced in a LAT promoter mutant virus,⁵⁸⁹ suggesting that the LAT promoter is bidirectional.

Expression of HSV-2 miR-H3 by transfection reduced ICP34.5 expression in transfected or infected cells,¹¹²⁶ whereas expression of HSV-1 miR-H2 reduced ICP0 expression and miR-H6 reduced ICP4 expression.¹¹⁶⁸ Thus, these microRNAs could contribute to latent infection by down-regulating critical viral gene products needed for lytic infection. A few studies have looked at the function of microRNAs when expressed from the virus; however, much remains to be done in this area. Tang et al¹¹²⁷ found that reduction in expression of HSV-2 miR-H6 did not result in any detectable phenotype with regard to acute or latent infection of guinea pigs.

Events of Latent Infection and Reactivation

We will now examine the mechanisms of latent infection in chronological order in more detail.

Establishment of Latency: Initial Stages

Electron microscopic studies indicate that in neurons infected in cell culture, the viral particle transported by retrograde transport along microtubules in the axon is the unenveloped nucleocapsid or nucleocapsid-tegument structure.^{691,861} Viral gene expression, α , β , γ , and LAT RNAs, are observed in ganglia of infected animals over the first 24 to 72 hours.^{583,586,1178} Several host immune response effectors are postulated to play a role in control of early viral replication, including IFN- γ , macrophages, $\gamma\delta$ T cells, and CD8⁺ T cells. CD8⁺ T cells infiltrate the ganglia starting around 5 to 7 days postinfection, coincident with the time at which virus starts to decrease around day 7.^{663,1037} CD8⁺ T cells have been shown to play an essential role in control of HSV replication in the nervous system¹⁰⁵⁰ and in controlling viral replication in the ganglia during acute times of infection.⁶⁶² Cytokine and chemokine expression increases in the acutely infected sensory ganglia.

The silencing of viral genes in sensory neurons appears to be a slow and multistep process. Although the events occurring during the first few hours after entry of viral DNA into dorsal root ganglia have not been defined (Fig. 60.16), a key factor is likely to be the reduced expression of α genes. The reduced α

FIGURE 60.16. Molecular events during establishment of and reactivation from latent infection. **A:** Viral DNA is bound by host proteins upon entry into the neuronal nucleus. **B:** Viral DNA is silenced by histone and repressor association. The question mark indicates that we know little about the precise mechanisms of this process. **C:** Latency-associated transcripts (LATs) and possibly microRNAs play roles in maintenance of viral chromatin silencing. **D:** Removal of nerve growth factor or explant leads to disordered viral gene expression and turnover of LAT and microRNAs.

gene expression is likely explained by several mechanisms acting in combination (see Fig. 60.16):

1. *Neuronal repressors.* The host Oct-2 factor was postulated to repress α gene expression through its interaction with

TAATGARATT sites blocking Oct-1 activation.^{540,651} However, other investigators could detect no Oct-2 expression in sensory neurons, and even when Oct-2 was overexpressed in cells, it did not inhibit expression from a complete α -promoter/enhancer-bearing reporter gene,⁴¹¹ reducing the potential for α gene repression by Oct-2. The neuron-specific Zhangfei factor has also been postulated to block activation of α gene promoters through interaction at Oct-1 binding sites.¹³ Similarly, expression of a dominant-negative form of the host repressor REST reduced viral replication in neurons,²⁹⁵ indicating that REST is part of the mechanism of silencing of the viral genome in neurons.

2. *Hormonally regulated repression of viral gene expression.* Nerve growth factor (NGF) treatment of sensory neurons has been shown to restrict viral lytic gene expression,¹²⁵⁹ and anti-NGF treatment of latently infected neurons increases viral lytic gene expression.²⁹⁵
3. *Lack of viral and cellular factors necessary to overcome host silencing and allow α gene transcription.* Several studies have raised the idea that sensory neurons lack essential factors for expression of HSV α genes, thereby explaining the latent infection in these cells. In studies using *in situ* hybridization to detect Oct-1 mRNA, it was found that Oct-1 is not expressed in cells of the sensory ganglia.^{435,1178} More sensitive assays showed Oct-1 and GABP α/β are present but at low levels in sensory neurons.⁴¹¹ Kristie et al.⁵⁹⁶ showed that HCF, or C1, the cellular co-factor required for enhancement of α gene expression along with Oct-1 and VP16, resides in the cytoplasm in trigeminal ganglion neurons and is translocated into the nucleus only under conditions of reactivation such as explantation of ganglia in culture; thus, HCF may not be capable of localizing to the nucleus when HSV infects and cannot transactivate α gene transcription. In addition, HCF has been reported to transport VP16 into the cell nucleus.⁶⁰⁷ Therefore, in sensory neurons, even if the VP16 in the incoming virion were translocated to the neuronal cell body, it would not be localized into the neuronal nucleus, and it could not participate in transactivation of α genes. Further, it has been proposed that VP16 from input virus particles is not translocated to the neuronal nucleus in the cell body to enter the nucleus or cannot function in some way to activate α gene expression in neurons.¹⁰²⁶ In support of this, the limited α gene expression in neuronal cells is reported to be independent of VP16.⁹⁰¹
4. *Viral RNA-mediated repression of α gene expression.* LAT-negative mutant viruses show elevated lytic gene expression in trigeminal ganglion neurons during acute infection at 3 to 5 days postinfection.³⁶⁰ Therefore, LAT or one of its products seems to exert some of its repressive effects at early times following infection of neurons.

It is informative to look at the kinetics of LAT and microRNA expression and accumulation. Expression of LAT is detected by 26 hpi in murine trigeminal ganglia⁵⁸⁶ and continues to increase for at least 3⁵⁸⁶ to 9 days postinfection.²⁹⁵ Similar levels and kinetics of LAT expression are observed for a TK-negative mutant virus, which does not replicate in TG neurons, indicating that LAT expression at these times largely occurs from input viral genomes.⁵⁸⁶ In one study, microRNAs were detected at 3 dpi in murine trigeminal ganglia at levels of 30 molecules/cell in one study and increased significantly

by 30 (dpi).⁵⁸⁹ Levels of LAT were much higher, approximately 1,000 molecules/cell, at 3 days post infection (dpi).⁵⁸⁹ In another study, microRNAs were detected by 1 dpi and continue to increase until approximately 9 dpi.²⁹⁵ In that study, levels of LAT and microRNAs were similar. Therefore, LATs and microRNAs could be expressed early enough to add to the repressive effects of pre-existing host repressors.

CHROMATIN SILENCING OF VIRAL LYTIC GENES

Chromatin assembly with incoming viral DNA is very rapid in cells in culture.²⁰⁷ In trigeminal ganglia, histone H3 association with HSV DNA is apparent by 7 dpi, and the H3K9me2 modification is apparent by 15 dpi.¹²¹⁴ Further studies have shown that whereas the viral lytic gene promoters are associated with H3 histone by 7 dpi, the H3K27me3 heterochromatin modification was not detected on HSV lytic gene chromatin until later, 14 dpi,²⁰⁵ arguing that the earliest chromatin effect is association of unmodified chromatin followed by the H3K27me3 modification. In this infection model, acute viral replication in the trigeminal ganglia has largely declined by 7 dpi⁶³¹; therefore, H3K27 methylation appears to occur after resolution of the infection. This would argue that events earlier than heterochromatin modifications of histones are responsible for the initial silencing of the viral genome.

Genetic analysis of viral mutant virus strains has attempted to define the role of viral gene products in establishment of latent infection. HSV must have access to the nerve endings in order to establish latency; therefore, it could be expected that the greater the number of peripheral cells that become infected and support virus multiplication, the larger the number of neurons that will harbor latent virus. Indeed, viruses that are replication defective show reduced levels of latent infection, although they can establish and maintain latent infections but not reactivate.^{211,535,1027} In essence, no deletion mutant totally failed to establish latent infection.

Studies on the neuronal subtype in which latent infection is established in murine model systems have shed light on the mechanisms of establishment of latent infection. In mice infected by the ocular route with HSV-1 strain KOS virus, latent infection is preferentially established in a subset of neurons identified with the A5 antibody recognizing a specific lactoseries glycoconjugate.¹²⁹² Further studies showed that HSV-2 preferentially established latent infection in KH10 MAB-reactive sensory neurons in either trigeminal or dorsal root ganglia.⁷⁰⁸ A recombinant HSV-2 virus that expresses the HSV-1 LAT showed an HSV-1 phenotype (i.e., preferential establishment of latency in A5-positive neurons),⁷⁰⁸ and a recombinant HSV-1 virus expressing the HSV-2 LAT showed an HSV-2 phenotype (i.e., preferential establishment of latency in KH10-positive neurons).⁴⁸⁵ These studies showed that LAT influenced establishment of latent infection in specific neuronal subtypes. Furthermore, studies of infection of murine adult sensory ganglion neurons *in vitro* have shown that A5-positive sensory neurons are nonpermissive for HSV-1 strains KOS and 17 *in vitro* but are permissive for HSV-2.⁸⁸ Although the LAT recombinant viruses were not examined in these studies, these studies, in total, raise the general model of LAT controlling productive infection in specific neuronal subtypes. Therefore, these studies support the idea that both viral and host factors contribute to establishment of latent infection.

The question of whether viral infection leads directly to latent infection versus lytic infection and/or whether lytic infection can convert to latent infection has been debated extensively. Studies using viruses that express CRE recombinase from viral promoters found that approximately one-third of the latently infected neurons have experienced immediate-early promoter activation prior to establishment of latent infection but have not experienced TK or VP16 promoter activation.^{900,901} This argues that at least α gene expression can precede latent infection and raises that possibility that these gene products could affect the host responses or viral chromatin and affect the type of latent infection that ensues.

Maintenance Phase of Latency

As described previously, extensive studies on ganglia harboring latent HSV have been rewarded by an extreme paucity of evidence for viral gene expression, except for LATs and microRNAs. Nevertheless, low-level expression of α ICP4 and β TK gene transcripts have been observed in murine trigeminal ganglia.⁵⁸⁷ ICP4 protein has been observed in rabbit trigeminal ganglia³⁹²; however, owing to the significant rate of spontaneous reactivation in rabbit TGs, the possibility that this was attributable to reactivation cannot be eliminated. Kramer and Coen⁵⁸⁷ hypothesized that the low level of lytic transcripts was likely owing to a low level of lytic gene breakthrough during latent infection, whereas others have found rare neurons in murine ganglia that express high levels of lytic transcripts, and they have hypothesized that the low levels of lytic transcripts observed in latently infected ganglia are attributable to a few cells undergoing reactivation rather than numerous cells showing low-level expression.³³⁰ Further studies looking at HSV transcript levels in individual neurons¹⁰⁰⁰ should determine the fraction of neurons that show expression of lytic transcripts.

There is prolonged expression of cytokines and chemokines^{151,185,225,413,1038} and CD8⁺ T-cell infiltration^{543,662} in the latently infected murine ganglia and prolonged expression of cytokines and chemokines in human latently infected ganglia.¹¹³⁸ This indicates that there is continued antigenic stimulation of dendritic cells (DCs) and macrophages and continued T-cell activation in the ganglionic tissue. As described elsewhere in this chapter, the ongoing immune surveillance is likely in response to the presence of viral antigens in the ganglion owing to low-level reactivation.

Heterochromatin likely plays an important role in maintaining the HSV lytic genes in a silenced state during latent infection,^{206,560,1214} whereas the LAT promoter and enhancer have euchromatin associated with them.⁵⁹⁷ How are these separate chromatin domains maintained? Amelio et al¹⁸ have identified candidate insulator elements containing CCTC factor (CTCF) binding sites at the U_L/c boundary (bp 120,503–120,635), and in the LAT intron (bp 117,158–117,342), and they propose that these insulators keep the LAT enhancer activity within that boundary and heterochromatin outside of those boundaries.

The latent HSV infection, in addition to inducing the recruitment of immune cells into the ganglia, leads to perturbation of neuronal host cell gene expression. Using microarray studies, Kramer et al⁵⁸⁸ showed that numerous cellular genes were up-regulated or down-regulated in latently infected murine trigeminal ganglia. Little is known about the effects of these gene expression changes on the host neuron.

COPY NUMBER OF VIRAL DNA IN LATENTLY INFECTED NEURONS

Early studies determined that there are between 0.1 and 1 viral genome equivalents per cell genome during latent infection.^{142,943,944} In calculations based on neurons accounting for only about 10% of the total cells in a sensory ganglion, it was obvious that each latently infected neuron must contain more than one viral genome.⁹⁵⁸ This was shown more directly in studies showing that approximately 20% of single purified murine trigeminal ganglion neurons contain viral DNA with an average of 20 to 30 HSV DNA molecules per cell and a range from less than 10 to greater than 1,000 molecules per cell.^{1000,1145} In studies of human neurons obtained by laser capture microdissection of trigeminal tissue, 2% to 10% of the neurons contain viral DNA with a median value of 11 genomes per cell and a range of 5 to 3,955 copies per cell.¹²¹³ The range of DNA copy numbers raises the issue of heterogeneity of latent infection in different cells. Furthermore, only 0.2% to 1.5% of the human TG neurons express LAT, as detected by *in situ* hybridization.¹²¹³ Thus, there are many more neurons containing DNA than expressing LAT, at least as detected by *in situ* hybridization. This extends the issue of heterogeneity of latent infection by demonstrating that some latently infected neurons have all viral genes but LAT silenced, whereas other neurons have the entire viral genome silenced. This raises another important issue: What contributes to the high levels of viral DNA molecules per neuron?

In terms of the events and mechanisms leading to the high copy number of viral DNA in latently infected cells, this could be owing to multiple viruses infecting each neuron. Alternatively, the viral DNA could be replicated by viral or cellular mechanisms. Studies using HSV mutant strains that do not replicate viral DNA in neurons, such as TK-negative viruses, do show lower levels of viral DNA per cell,^{1058,1145} supporting the idea that viral DNA replication contributes to the levels of DNA in the latently infected neuron. Nevertheless, even the ganglia infected with TK-negative mutant viruses contain multiple genomes per cell, so there may be some leaky viral DNA replication in these cells or there is still the potential for infection by multiple viruses or that nonviral replication mechanisms contribute to the levels of viral DNA.⁹⁵⁸

Reactivation of Virus From the Latent State

As described earlier, there are several experimental systems for studying *in vitro* and *in vivo* reactivation. Upon induction of reactivation by *in vitro* explant, LAT and microRNA transcript levels decrease and lytic gene transcripts increase,^{295,584,1083} and the histones associated with the *LAT* gene become deacetylated.¹⁷ Similarly, lytic genes such as the *ICP0* gene become associated with acetylated histones,¹⁷ and lytic gene transcripts accumulate.^{273,584} The assumption has been that viral gene expression during reactivation follows the α - β - γ paradigm, and some evidence has supported this.^{273,584} However, Tal-Singer et al¹¹²⁴ reported that they could detect β gene expression prior to α gene expression during explant reactivation. In this study, they used RT-PCR to detect viral transcripts but did not show that the assays for each of the transcripts was equally sensitive; thus, it is conceivable that the differences in kinetics of appearance reflected sensitivity of the detection assay rather than the true order of appearance. Some *in vivo*^{583,584} and cell culture⁸⁰⁶ studies have suggested that optimal viral gene expression in neurons depends on viral DNA replication, although

viral spread was not ruled out in the *in vivo* and *ex vivo* studies. However, as first suggested by Sawtell and Thompson¹⁰⁰¹ and then shown by Pesola et al⁸⁷¹ and Sawtell et al,¹⁰⁰³ when viral spread is prevented, there is no apparent role for viral DNA synthesis in stimulation of α and β gene expression in the explant situation. Nevertheless, one study of infection of sensory neurons in culture does support the idea that viral gene expression in neurons is affected by viral DNA synthesis, in that Nichol et al⁸⁰⁶ observed that in HSV-infected sensory neurons in culture, viral DNA synthesis stimulates α and β gene expression.

The events leading to viral gene expression during reactivation continues to be debated. Thompson and Sawtell¹¹⁴² have defined the exit from latency as the expression of viral lytic proteins as detected by immunohistochemistry using anti-HSV antiserum, and they defined reactivation as the production of infectious virus. In the transient hyperthermia reactivation model, they observe an average of one cell per ganglion in which virus has escaped latency and approximately 70% of the ganglia reactivate with an average yield of 10 pfu of virus per ganglion.¹¹⁴² An ICP0 mutant showed similar escape from latency but no reactivation. Thompson and Sawtell¹¹⁴² concluded that ICP0 does not initiate reactivation from latency *in vivo*; however, the process of exit of latency in this system is of low efficiency and could have minimized the differences between wild-type and mutant viruses.

A second study in this *in vivo* reactivation system tested the ability of a VP16 mutant virus—*in1814*—to reactivate and found that the *in1814* virus reactivated in *in vitro* explant but not in the *in vivo* reactivation system.¹¹⁴¹ They concluded that VP16 is needed for *in vivo* exit from latency but not in *in vitro* explant. They argued that VP16 is expressed prior to the immediate-early proteins; however, VP16 promoter activity was measured by β -galactosidase staining, whereas viral proteins were measured by immunohistochemistry, and β -gal staining may be more sensitive. This interesting hypothesis merits further investigation.

A recent study found that in explanted ganglia incubated with anti-NGF antibody with or without cycloheximide, viral genes of α , β , and γ kinetic classes, including VP16, are expressed simultaneously and not sequentially ordered.²⁹⁵ The RT real-time PCR assays used in this study provide more sensitive assays than protein detection, and this may explain the differences between this study and the two previous ones. Similar results were obtained in an *in vitro* neuronal latent infection system that showed an initial widespread derepression of viral genes prior to VP16-dependent transcription.⁵⁴⁷ These results argue that reactivation from a state of heterochromatin over the entire genome occurs by cellular mechanisms affecting the entire genome uniformly and emphasize the differences in the mechanisms of reactivation versus initial infection of neurons and other cell types.

In humans, latent virus is reactivated after local stimuli such as injury to tissues innervated by neurons harboring latent virus, or by systemic stimuli such as physical or emotional stress, hyperthermia, exposure to UV light, menstruation, and hormonal imbalance, which may reactivate virus simultaneously in neurons of various ganglia (e.g., trigeminal and sacral). A modest amount of evidence and the most plausible common denominator is that injury or stimulation of cells innervated by dorsal root neurons harboring latent virus is a common trigger of recrudescence of lesions caused by reactivated virus.

The important question of the nature of the transduced signal remains to be answered.

The fate of the neurons after viral reactivation is a hotly debated topic. Proponents of the notion that neurons survive to reactivate again and again base their arguments on two observations. The first is that local anesthesia is not a sequelae in patients suffering from frequent recurrences at the same site. A formal rebuttal of this argument is that nerve endings from adjacent unaffected neurons grow into the healed area and re-establish a network.

The second and more significant observation is that women with recurrent genital lesions shed virus in the interim between clinically manifest lesions. The shed virus appears to originate from punctate, microscopic lesions that arise frequently and for long intervals. If each microscopic lesion arises from a reactivated neuron, there would not be enough neurons to support viral reactivation over many years if the neurons perish as a consequence of this process. The question that has not been resolved is whether each lesion is the consequence of reactivation and whether chronic infections of mucosal tissues characterized by the observed microscopic lesions can be ruled out.

ASSEMBLY OF PROGENY VIRUS IN NEURONS

As described earlier, reactivation leads to expression of sufficient viral proteins and viral DNA replication to produce some progeny virions. These are ultimately released at the axonal termini to initiate the recurrent infection at the site of innervation of the nerve. The mechanisms of assembly of HSV progeny virions in neurons has been controversial, as there has been evidence of intact viral particles undergoing anterograde transport as well as evidence of independent transport of capsids and vesicles containing the viral glycoproteins.^{26,1268} New components of the virion move by anterograde transport to both peripheral and central branches of the neuron.⁶²³ Virion assembly and/or release have been reported along the axon shaft and at the axon tip.^{826,984,1153} The question is how virions or virion components are transported by anterograde transport to these sites of virion release. Early studies of HSV infection of human fetal neurons followed by electron microscopy, immuno-electron microscopy, and immunofluorescence analyses concluded that capsids are transported independently from vesicles containing viral glycoproteins.^{457,861} Immunofluorescence and live cell imaging of human neuroblastoma cells infected with HSV also showed separate sites of staining or localization for glycoproteins relative to capsid proteins.^{1065–1067} A further study using high-resolution electron microscopy has shown that 75% of the capsids in the axons of rat neurons were in virion particles.⁷⁹⁵ Recent studies of “two-color” HSV recombinants expressing fluorescent capsid proteins and a fluorescent glycoprotein have continued to find different results, in that one study found that 64% to 70% of the capsids were associated with glycoproteins while undergoing anterograde transport,²⁶ although the other found that 80% and 67% of the capsids in two neuronal systems were independent of glycoproteins.¹²⁶⁸ Thus, there is the potential that either of two mechanisms of transport could occur to different extents in different neuronal cells under different conditions. Genetic studies have provided some insight in this area. One study has shown a defect in transport of envelope proteins, VP22 tegument, and VP5 capsid proteins into the optic nerve in mice infected with a glycoprotein E-negative virus,¹²¹²

implying that axonal localization of certain glycoproteins and capsid and teguments may be linked.

ROLE OF THE HOST IMMUNE RESPONSE IN LATENCY

The role of the host immune response in controlling acute lytic infection is clear; however, its role in latent infection is less clear. It has been reported that viral CD8⁺ T cells and/or IFN- γ can block viral gene expression and replication, leading to reactivation in explanted ganglia.^{259,661,662} There were sufficient HSV-specific T cells in acutely infected ganglia to control reactivation in explanted ganglia but not in latently infected ganglia.⁶⁶² Despite the latter results, the prolonged CD8⁺ T-cell infiltrate in latently infected ganglia has led to the proposal that CD8⁺ T cells “control” latency.⁵⁴⁴ Although some studies have attempted to correlate T-cell infiltrates with LAT-positive neurons,^{1138,1189} a recent study found that most LAT-positive neurons do not have CD3⁺ T cells around them. This study concluded that “the majority of LAT⁺ neurons is not directly controlled by T cells”.⁴⁴⁰ Therefore, we favor the idea that latent infection is maintained by neuronal and viral factors such as LAT and microRNAs, and CD8⁺ T cells are activated and retained in the ganglia in response to low-level expression of viral antigens. Supporting the idea that immune responses do not control latency, Gesser et al³⁷⁰ showed that HSV can establish latent infection in immunodeficient animals. Furthermore, van Lint et al¹¹⁸² observed that CD8⁺ T cells nonspecifically traffic into latently infected ganglia, although only the HSV-specific CD8⁺ T cells are activated and specifically retained in the ganglia. It seems likely that the host immune mechanisms respond to and control lytic infection and that latent infection of neurons involves intrinsic nonpermissive properties of sensory neurons and viral functions.

PATHOGENESIS OF HUMAN INFECTION

Transmission of HSV depends on intimate, personal contact between a seronegative (susceptible) individual and someone excreting HSV. Virus must come in contact with mucosal surfaces or abraded skin for infection to be initiated. Following oropharyngeal infection, usually caused by HSV-1, the trigeminal ganglion becomes colonized and harbors latent virus. Acquisition of HSV-2 infection is usually the consequence of transmission by genital contact. Virus replicates in the genital, perigenital, or anal skin sites with seeding of the sacral ganglia.

Accumulated clinical experience suggests that after primary infection, replication of virus at the portal of entry, usually oral or genital mucosa, results in infection of sensory nerve endings; virus is transported to dorsal root ganglia.^{65,70,1097} The more severe the primary infection, as reflected by the size, number, and extent of lesions, the more likely it is that recurrences will ensue. This notion is attributed to the large quantity of virus present when primary disease is extensive as compared with asymptomatic infections.

Fundamental to disease pathogenesis is the propensity of virus to replicate at mucosal surfaces, to be transported to dorsal root ganglia, and to become latent. Although replication can sometimes lead to disease and can infrequently result in life-threatening CNS infection, the host–virus interaction leading to latency predominates. With reactivation, virus is detected at mucocutaneous sites, appearing as skin vesicles or mucosal ulcers, or can simply be excreted in the absence of symptoms.

Primary infection can spread beyond the dorsal root ganglia, thereby becoming systemic. For example, studies of children with primary gingivostomatitis demonstrated HSV DNA in the blood by PCR in about one-third of patients.⁴⁷² Similarly, 24% of adults with primary genital herpes had viral DNA detected by PCR in the blood.⁵¹⁶ Multiorgan disease is encountered in disseminated neonatal HSV infection, visceral organ disease of pregnancy, and, rarely, in immunosuppressed patients.

For individuals susceptible to HSV infections (namely, those without pre-existing antibodies), the first exposure to either HSV-1 or HSV-2 results in primary infection. The epidemiology and clinical characteristics of primary infection are distinctly different from those associated with recurrent infection. Reactivation of HSV is known as recurrent infection and clinically results in a limited number of vesicular lesions, as occurs with HSV labialis or recurrent HSV genitalis. An individual with pre-existing antibodies to one type of HSV (i.e., HSV-1 or HSV-2) can experience a first infection with the opposite virus type (i.e., HSV-2 or HSV-1, respectively) at a different site. Under such circumstances, the infection is known as an initial infection rather than as a primary infection. For example, an initial infection occurs in those individuals who have pre-existing HSV-1 antibodies who then acquire a genital HSV-2 infection. Because many individuals are infected with HSV and do not experience a primary infection, the first recurrence has been identified as first episode infection. Reinfection with a different strain of HSV occurs, although it is uncommon in the normal host.

UNIQUE BIOLOGICAL PROPERTIES OF HERPES SIMPLEX VIRUS

HSV has two unique biological properties: neurovirulence and latency. The propensity of HSV to invade and replicate in the CNS can result in profound disease with severe neurologic devastation, as occurs with HSV encephalitis. Alternatively, virus simply establishes latency, providing a reservoir for virus transmission to susceptible persons if reactivated.

Neurovirulence

Neurovirulence encompasses both neuroinvasiveness from peripheral sites and the ability of HSV to replicate in neuronal cells. Whereas this property may be the function of numerous genes, the deletion of one gene in particular, $\gamma_134.5$, removes the ability of HSV to both invade and replicate in the CNS, as defined earlier.

Predictably, mutations affecting neuroinvasiveness have also been mapped in genes encoding glycoproteins. Access to neuronal cells from usual portals of entry into the body requires postsynaptic transmission of virus and, therefore, a particularly vigorous capacity to multiply, being dependent on glycoprotein expression. In addition, because neuronal cells do not make cellular DNA, they lack the precursors for viral DNA synthesis that are also encoded by those viral genes that are dispensable for replication in cell culture.

Latent Infection in Humans

Latent virus has been retrieved from the trigeminal, thoracic, sacral, and vagal ganglia of humans.^{65,70,1221} As but one example, virus isolation was attempted from the trigeminal ganglia of 90

cadavers and was documented in 44 individual situations. In 26 of these cases, HSV was isolated bilaterally from both ganglia. Similarly, when 68 sacral ganglia were co-cultivated, only 9 were positive and all for HSV-2.

Patients treated for trigeminal neuralgia by sectioning a branch of the trigeminal nerve can develop herpetic lesions along the innervated areas of the sectioned branch.^{162,243,387,855,856} Microvascular surgery of the trigeminal nerve, performed to alleviate the pain associated with tic douloureux, resulted in recurrent herpetic lesions in more than 90% of seropositive individuals.

Reactivation of latent virus depends on an intact anterior nerve route and peripheral nerve pathways. Induction of viral replication by axonal injury¹²¹¹ follows sectioning of a peripheral nerve and results in the appearance of virus within the ganglia 3 to 5 days after the surgical manipulation. Not surprisingly, if an attempt is made to excise the lesions induced by HSV, vesicles will recur adjacent to the site of excision. Recurrences occur in the presence of both cell-mediated and humoral immune responses. Recurrent herpes labialis is three times more frequent in febrile patients than in nonfebrile controls.

PATHOLOGY

The pathologic changes induced by HSV replication are similar for both primary and recurrent infection but vary in the extent. The histopathologic characteristics of HSV skin lesions are shown in Figure 60.17,⁹⁵⁶ representing a combination of virus-mediated cell death and associated inflammation. Viral infection induces ballooning of cells and the appearance of condensed chromatin within the nuclei of these cells, followed by subsequent degeneration of the cellular nuclei, generally within parabasal and intermediate cells of the epithelium. Cells lose intact plasma membranes and form multinucleated giant cells. With cell lysis, clear (referred to as vesicular) fluid containing virus appears between the epidermis and dermal layer. The vesicular fluid contains cell debris, inflammatory cells, and, often, multinucleated giant cells. In dermal substructures, there is an intense inflammatory response, usually in the corium of the skin. With healing, the vesicular fluid becomes pustular with the recruitment of inflammatory cells and then it scabs. Scarring is uncommon but has been noted in some

FIGURE 60.17. Histopathology of herpes simplex virus infection.

FIGURE 60.18. Perivascular cuffing with areas of hemorrhagic necrosis of brain.

patients with frequent recurrences. When mucous membranes are involved, vesicles are less likely to be prominent. Instead, shallow ulcers are more common because the vesicles rapidly rupture as a result of the very thin cornified epithelium.

Vascular changes in infected tissue include perivascular cuffing and areas of hemorrhagic necrosis⁹⁵⁶ (Fig. 60.18). These histopathologic findings become particularly prominent when organs other than skin are involved, such as HSV encephalitis or disseminated neonatal HSV infection. In these cases, widespread areas of hemorrhagic necrosis, mirroring the area of infection, are prominent. When the brain is involved, oligodendrocytic involvement and gliosis are common, as is astrocytosis; however, these changes develop late in the disease course. Local lymphatics can show evidence of infection with intrusion of inflammatory cells, draining infected secretions from the area of viral replication. The intensity of the inflammatory response is significantly less with recurrent disease. As host defenses develop, an influx of mononuclear cells is detected in infected tissue.

MODELS OF DISEASE PATHOGENESIS

Animal models allow study of the pathogenesis of infection outside the human; however, herein lies a series of fundamental problems. The animal species (indicative of susceptibility), virus species, route of infection, state of immune competence, and specific viral strain all influence disease pathogenesis. Both HSV-1 encephalitis (virulence) and latency models have been established following inoculation by the eye route. However, the endpoints of virulence and latency do not routinely correlate with human disease. After ocular inoculation by corneal scarification, replication of virus in the eye peaks within 48 hours and declines over the next 6 days. Virus appears in the trigeminal ganglia approximately 1 day after inoculation, with peak replication occurring 4 to 6 days later. If sufficient quantities of virus and/or a virulent strain of virus are inoculated onto the eye, encephalitis follows virus replication within the trigeminal ganglia.⁵⁶³

For HSV-1 cutaneous infections, mice (particularly the hairless mouse)¹¹⁷¹ and rabbits or guinea pigs with abraded or punctured skin are used to study replication and disease pathogenesis as well as to evaluate antiviral therapies. The hairless mouse, guinea pig, and rabbit are all artificial models of human cutaneous infections, particularly for recurrent infections of humans.

HSV-2 mucosal infections have been studied most extensively in an intravaginal guinea pig model. Both HSV-1 and

HSV-2 have been used in this model. These animals tend to experience continual recurrences of lesions; however, retrieval of HSV from these lesions is variable. The guinea pig genital infection model has been used extensively in the assessment of vaccines and antiviral drugs, although infection of cotton rats with HSV-2 has also been shown to cause recurrent genital disease, albeit less well characterized.¹³⁰⁰

Models of life-threatening disease include the intranasal inoculation of HSV-1 or HSV-2 in young (3-week-old) Balb/C mice, resulting in CNS and visceral (usually lung) disease (mimicking neonatal HSV infection). However, inoculation of older mice with similar quantities of either virus may fail to cause disease, or, if it does lead to disease, it might be encephalitis but not multiorgan disease. Intracerebral inoculation of virus provides an unnatural route of infection even for the study of antiviral therapeutics; however, it is used to screen new drugs.

Accurate and predictive models of human HSV encephalitis have been described using rabbit^{1009,1010} and mouse models. The resultant disease leads to focal localization of infection in the rabbit brain, as compared with diffuse pancortical infection of the mouse brain. Virus is inoculated directly into the olfactory bulb or upon abraded nasal epithelium of the rabbit over the nerves from the olfactory bulb.¹¹⁰⁶

Human models of both labial and genital herpes have been reported. Induced reactivation of HSV labialis occurs by exposure of the vermillion border of the lip of seropositive individuals to UV light.⁹⁶⁶ The resulting lesions and course of infection are similar to those that occur naturally. Lesions develop in approximately 70% of UV-exposed volunteers after approximately 3 days. This model has been exploited for the evaluation of antiviral therapies.^{966,967} Similarly, UV exposure of the buttocks and thigh in HSV-2-infected individuals results in reactivation in approximately 35% and a longer incubation period of about 5 days.⁹⁶⁷

EPIDEMIOLOGY

Orolabial Herpes Simplex Virus Infections: Primary and Recurrent

HSV is distributed worldwide and have been reported in both developed and underdeveloped countries, including remote Brazilian tribes.^{96,676} Humans are the sole reservoir for transmission of HSV to other humans. Virus is transmitted from

infected to susceptible individuals during close personal contact. There is no seasonal variation in the incidence of infection. Because infection is both rarely fatal and these viruses become latent, over half of the world's population has been infected by HSV and, therefore, is capable of transmitting HSV during episodes of productive infection.

Geographic location, socioeconomic status, and age are the primary factors that influence the acquisition of HSV infection, regardless of the mode of assessment.^{281,1025} In developing countries and lower socioeconomic populations, infection occurs early in life. By 5 years of age, approximately one-third of children seroconverted, increasing to 70% to 80% by early adolescence.^{97,784} Predictably, middle-class individuals of industrialized societies acquire antibodies at a later age in life. Seroconversion occurred over the first 5 years of life in 20% of children, followed by no significant increase until the second and third decades of life, at which time the prevalence of antibodies increased to 40% and 60%, respectively.^{380,726,999,1063,1232} Seroconversion of susceptible university students occurs at an annual frequency of approximately 5% to 10%.^{373,380}

Examples of early lessons on the epidemiology and pathogenesis of infection are in order. Following the association of HSV and gingivostomatitis,^{141,281} virological screening was used to study the epidemiology and natural history of infection. Primary infection led to the shedding of virus in mouth and stool and from the former site for as long as 23 days (average, 7 to 10 days).^{21,281} Neutralizing antibodies appeared between 4 and 7 days after the onset of disease and peaked in approximately 3 weeks. Virus was isolated from the saliva of asymptomatic children, occurring in approximately 20% of the children in the age range of 7 months to 2 years.¹³⁶ Despite no overall race or sex differences, young African American children had higher rates of both neutralizing antibodies and virus isolation than did their Caucasian counterparts. Virus shedding in children younger than 6 months was uncommon, as has been noted in more recent studies.⁵²² In older children, 3 to 14 years of age, asymptomatic shedding was documented in 18%. Retrieval of infectious virus decreased with advancing age, being only 2.7% in individuals more than 15 years of age. These frequencies of shedding are similar to contemporary cross-sectional surveys, ranging from 2% to 5%.⁹⁵⁶ Application of more contemporary technology, namely PCR, demonstrates higher frequencies of shedding and for intermittent periods.⁷⁰⁹

The influence of age is underscored by other studies. Evidence of oral herpetic infection was found in approximately 13% of children over a 10-year period. Children 1 to 2 years of age were most commonly infected, accounting for more than half of all cases. No differences in sex or seasonal variation were detected.^{260,956} Most children experienced asymptomatic infection, accounting for more than 65% of all cases.^{23,172}

With the development and licensure of species-specific serologic assays, the seroprevalence of HSV-1 and HSV-2 infections was redefined using sera obtained from two randomized National Health and Nutrition Examination Surveys (NHANES).^{335,787} The seroprevalence of HSV-1 is more common than HSV-2. By 5 years of age, more than 35% of African American children versus 18% of Caucasian children are infected with HSV-1. No significant differences in seroprevalence exist between the three studies: one performed on sera collected in 1978 and the other between 1988 and 1994. Subsequently, through adolescence, African Americans had approximately a twofold higher prevalence of antibodies to

HSV-1 than did Caucasians, and females had a slightly higher prevalence than did males. Furthermore, the prevalence of HSV-1 was slightly higher for females than males. By 40 years of age, both African Americans and Caucasians had similarly high prevalence of antibodies, in excess of 60%.^{1279,1280}

When similar analyses were performed on populations from various countries around the world, notable differences have been detected. For example, only 5 of 18 countries surveyed had an HSV-1 antibody prevalence of less than 70%. Antibody prevalence in excess of 95% was detected for adults 20 to 40 years of age in Spain, Italy, Rwanda, Zaire, Senegal, China, Taiwan, Haiti, Jamaica, Uganda, and Costa Rica. Thus, a high prevalence of antibodies to HSV-1 exists worldwide; however, there is significant country-to-country variation.^{484,676}

In summary, these studies demonstrate a significantly lower prevalence of antibodies during childhood, adolescence, and even later in life among relatively middle and upper socioeconomic classes. Primary infection occurs much earlier in life, generally very early, in children of the developing world as well as in those of lower socioeconomic classes, whereas in developed countries and more affluent classes, primary infection may be delayed until adolescence or perhaps even adulthood. The frequency of direct person-to-person contact, indicative of crowding encountered with lower socioeconomic status, appears to be the major mediator of infection.

The largest human reservoir of HSV-1 is latent infection in the trigeminal ganglia, which reactivates leading to recurrent herpes labialis. Studies performed to assess the frequency and severity of recurrent infection in the immunocompetent host are limited. A positive history of recurrent herpes labialis was noted in 38% of 1,800 graduate students.^{1041,1042} New lesions occurred at a frequency of one per month in 5% of the afflicted students and at intervals of 2 to 11 months in 34% of the afflicted students. Recurrences of one per year or less often were found in 61%. The predictable frequency of recurrence is relatively constant—approximately 33% in several studies.^{352,1039,1040} Lower frequencies of recurrences have been reported (16%); however, under vastly different socioeconomic conditions (upper vs. lower socioeconomic conditions) than previous studies.^{290,1303} Ironically, one other study found that recurrences occur more frequently among the more socially privileged,¹⁰⁴⁰ suggesting more attention to relatively trivial medical illnesses.

Recurrent infection occurs in the absence of clinical symptoms. Asymptomatic excretion of HSV in healthy children is about 1% to 5%.^{380,1238} Nearly 1% of pregnant women and nursery personnel excrete HSV at any time, providing a source of virus for transmission to the newborn. Asymptomatic excretion of virus is not limited to the healthy adult, occurring in nearly one-third of seropositive transplant recipients.^{172,851,852}

Unusual Epidemiologic Infections

Clustered outbreaks of human HSV infections have been reported; however, there is no indication from either clinical or molecular epidemiologic studies that HSV causes epidemics. Most studies involved families in which several individuals had HSV infection at approximately the same time. No index case could be identified, although recurrent labial lesions of one family member were frequently incriminated.

Outbreaks within hospitals have been identified, yet here also, no clear epidemic nature of the disease could be determined.^{412,903} Herpetic stomatitis outbreaks have been

reported within orphanages,^{412,522} where the attack rate for apparent primary infections was approximately 75% of the susceptible patients. Similarly, an outbreak of HSV encephalitis was recognized in Boston; however, no common virus was identified.⁴¹⁶ Interestingly, increased transmission of HSV in daycare centers has not yet been reported to be problematic.¹⁰¹²

Genital Herpes Simplex Virus Infections: Primary and Recurrent

Genital herpes can be caused by either HSV-1 or HSV-2. Because infections with HSV-2 are usually acquired through sexual contact, antibodies to this virus are rarely found before the onset of sexual activity.¹²⁷⁸ Importantly, an ever-increasing proportion is attributable to HSV-1.^{531,1273} Indeed, more than 50% of primary episodes of genital herpes at some sexually transmitted disease (STD) clinics are caused by HSV-1.¹²⁷⁸ The distinction in virus species is not insignificant; genital HSV-1 infections are usually both less severe clinically and less prone to recur.^{231,928} Sexual transmission of both viruses is the consequence of intimate contact, namely oral–genital or genital–genital.^{552,1238}

The most accurate assessment of the prevalence of HSV-2 infections is derived from species-specific serologic assessments of targeted populations. From the most recent NHANES study, the overall seroprevalence of HSV-2 in the United States is about 17%, as illustrated in Tables 60.1 and 60.2.^{335,1280} A rate of more than 20% was reported for middle and upper socioeconomic classes as well.⁶³⁶ This rate of infections was similar to that reported in the 1997 NHANES study.³³⁵ As many as 50% to 60% of lower socioeconomic women in the United States and elsewhere develop antibodies to HSV-2 by adulthood.^{335,788} Antibodies to HSV-2 are virtually nonexistent in nuns.⁹²⁴ This compares with similar data from Birmingham, Alabama, whereby seroprevalence was 11.4% in 1985 and 28% in 1990. Sera collected from pregnant women in the mid-1980s from Padova, Italy, Orebro, Sweden, and Stockholm, Sweden showed seroprevalence

rates varying between 8% and 28%. In contrast, 10% to 20% of women in higher socioeconomic groups are seropositive. Seroprevalence continues to increase over time, indicating widespread acquisition of HSV-2 infection. Factors found to influence acquisition of HSV-2 include gender (greater for women than for men), race (more frequent among African Americans than for Caucasians), marital status (more for divorced individuals than for single or married individuals), crowded personal living conditions, and place of residence (more in the city than in the suburbs). Importantly, the number of sexual partners correlates directly with probability of acquiring HSV-2 infection.⁵⁵²

The highest prevalence of antibodies to HSV-2 in the United States was identified in female prostitutes (75%)—a rate almost identical to that of prostitutes in Tokyo.⁷⁸⁷ Seropositivity among female prostitutes in Dakar, Senegal, was even higher, at 95.7% in 1985. Homosexual men have seroprevalence rates to HSV-2 varying from a high of 83.1% in San Francisco (1985–1986) to lows of 21.6% in Seville, Spain (1985–1986); 24.2% in Tokyo (1988); and 50.0% in Amsterdam (1986). Seroprevalence is higher in STD clinics, as would be expected.³⁹¹ The implications for HIV and STD risk reduction have also been addressed.³⁹⁰ Numerous seroprevalence studies have been reported.^{787,1007,1278} Some countries have surprisingly low HSV-2 seroprevalence rates. For example, in Italy, whereas the seroprevalence was high in STD clinics (26%), it was significantly lower in obstetric populations of Modena, being only 5.3%.²⁴⁴ An excellent review summarizes HSV-2 trends.⁷⁰³

As noted, the number of different sexual partners correlates directly with acquisition of HSV-2.⁷⁸⁷ For heterosexual women living in the United States having one partner, the probability of acquisition of HSV-2 is less than 10%. The probability increases to 40%, 62%, and greater than 80% as the number of lifetime sexual partners increases from 2 to 10, from 11 to 50, or greater than 50, respectively. For heterosexual men, similar data are 0% for one lifetime sexual partner and 20%, 35%, and

^aTotals differ from the numbers for whites and blacks because other races and ethnic groups are included in the category of all races and ethnic groups.

70% for each of the subsequent three risk groups. In contrast, for homosexual men, seroprevalence increases from greater than 60% to 90% for those with 11 to 50 and more than 50 partners. Thus, multiple sexual partners (*polypartnerism*), irrespective of sexual preference, correlate directly with acquisition of HSV-2 infection.⁷⁸⁷ In addition, male circumcision has been shown to decrease the risk of acquisition of both HSV-2 and HIV.¹²²⁷

Overall, the number of new cases of genital HSV infections has been conservatively estimated to be approximately 500,000 individuals per year.⁷⁸⁸ Estimates of individuals with genital herpetic infection in the United States are 40 to 60 million individuals.^{488,552,701}

Vaccine and recent antiviral studies have defined the risk of transmission.^{234,621} Several observations are relevant. First, women remain more susceptible to HSV infection than men. Second, transmission usually occurs from an asymptomatic individual and does so in more than 70% of cases. Third, overall, the annual rate of transmission is approximately 4% to 5% per annum. The rate of acquisition by women is about 8% annually, whereas it is lower for men at about 2%.

As with HSV-1 infections of the mouth, HSV-2 can be excreted in the absence of symptoms at the time of primary, initial, or recurrent infection.^{923,1161,1207} Among women evaluated prospectively after their first episode of genital herpes, asymptomatic shedding was detected in approximately 12%, 18%, and 23% of women with primary HSV-1, primary HSV-2, and first-episode HSV-2 infection, respectively.⁵⁶⁵ Among women with established genital HSV-2 infection, asymptomatic shedding was detected on 1% to 4% of all days that cultures were obtained.¹²⁴ Shedding of virus occurs more frequently in the first year following genital infection than in subsequent years.¹²⁰⁶ Seropositive individuals with no history of lesions shed virus as frequently as those who are symptomatic.¹²⁰⁷ Asymptomatic shedding is the most significant source for virus transmission.

The use of PCR to detect virus shedding markedly increases these rates, as is discussed later.

The incidence of HSV-2 infection has been assessed prospectively in selected populations. Among low-risk individuals, namely college students, the rate of acquisition was approximately 2% per year over 4 years, compared with 4% per year for homosexual men.⁷⁸⁷ The incidence of HSV-2 infection during pregnancy is about 2.5% per gestation but was reported by other investigators to be as low as 0.58%.¹¹³ As noted earlier, acquisition of HSV-2 infection between monogamous sexual partners with discordant infection status is about 5% yearly.⁷⁴⁵

Latent infection of sacral ganglia is the largest reservoir of HSV-2, and reactivation of this virus leads to recurrent HSV-2 infection. Recurrent HSV-2 infection, like HSV-1, can be either symptomatic or asymptomatic. A recurrence is associated with a shorter duration of viral shedding and fewer lesions.²³¹ The frequency of recurrences varies somewhat between males and females, with calculations of 2.7 and 1.9 per 100 patient-days, respectively.²³¹ Detecting HSV by both culture and PCR, viral excretion was documented at 6% annually; however, PCR detection of viral DNA occurred on 18% to 25% of days—a three- to fourfold increase over viral culture. Notably, there was an association between detection of virus by PCR (but not by culture) and person-to-person transmission.^{1161,1207}

Overall, several studies have reported a frequency of recurrence as high as 60%.¹⁷⁶ Broadly, nearly 90% of HSV-2-infected patients will have 1 or more recurrences per year, 38% will have 6 recurrences, and 20% more than 10 recurrences.⁸⁰ The type of genital infection (HSV-1 or HSV-2) is predictive of the frequency of recurrence.⁹²⁸ HSV-1 infection recurs less frequently than does HSV-2 infection.^{80,610} The changing prevalence of HSV-2 infections is illustrated by surveys of representative populations (Table 60.3).

TABLE 60.3 Prevalence of Herpes Simplex Virus 2 Antibodies in Different Populations

Site of study	Year(s) of study	Percent prevalence of HSV-2 antibodies
<i>Different individuals</i>

HSV-2, herpes simplex virus 2.

Herpes Simplex Virus and Human Immunodeficiency Virus Interactions

HSV-2 infection, by the nature of being an ulcerative disease, is associated with increased risk of acquisition of both human immunodeficiency virus type 1 (HIV-1) and human T-cell lymphotropic virus type 1 (HTLV-1) by one-and-one-half- to more than threefold,^{349,1205} in particular in regions where HIV and HSV-2 are both epidemic (Fig. 60.19). The association between acquisition of HIV-1 and HSV-2 has been documented in heterosexual populations, as well.¹⁶⁷ Although treatment with HSV

drugs reduces HIV blood levels,⁷⁸² a clinical trial of acyclovir failed to prevent HIV acquisition,¹⁶⁷ and a clinical trial of acyclovir in HSV seropositive individuals exposed to HIV-infected partners failed to prevent transmission.¹⁶⁸ Arguably, there is evidence of submucosal replication of virus and inflammation that led to the acyclovir failure.^{349,783,1322} Furthermore, a recent study showed that acyclovir blood levels are lower in African subjects than non-African subjects.⁶⁸⁴ Therefore, further studies are needed to determine the optimal drug concentrations needed for international use and to define an efficacious genital herpes vaccine for use in studies to prevent genital herpes as well as to prevent HIV acquisition in high-risk areas for HIV infection.

Molecular Epidemiology

Studies on isolates based on restriction enzyme polymorphism showed that viruses isolated from epidemiologically related individuals (parents and child, sexual contacts, hospital contacts, etc.) cannot be differentiated from each other. In contrast, isolates from epidemiologically unrelated individuals can be readily distinguished on the basis of the restriction endonuclease patterns of their DNA. In a small number of cases, it has been shown that the isolates consist of a mixture of viruses with different restriction enzyme patterns.^{133,134} These rare cases suggest that under some circumstances an individual may become infected with multiple strains of HSV.^{617,1011}

Maternal Genital Herpes Simplex Virus Infections

Genital HSV infection in the pregnant woman is as common as in age-matched, nonpregnant women. However, it must be considered separately because of the risk to fetus and newborn.⁴⁰⁶ An uncommon problem encountered with HSV infections during pregnancy is that of widely disseminated maternal disease.¹²³⁸ In a limited number of cases, dissemination after primary oropharyngeal or genital infection has led to life-threatening disease, such as necrotizing hepatitis with or without thrombocytopenia, leukopenia, disseminated intravascular coagulopathy, and encephalitis. The mortality rate among these pregnant women is reported to be greater than 50%. Fetal deaths also have occurred in more than 50% of cases, although mortality did not necessarily correlate with the death of the mother. Surviving fetuses

FIGURE 60.19. Numbers of cases of herpes simplex virus 2 infection in 2003 (red)⁶⁷⁶ and persons living with human immunodeficiency virus in 2009 (black) (UNAIDS) globally. (Copyright David Knipe.)

were delivered by cesarean section either during the acute illness or at term, and none had evidence of neonatal HSV infection. Fortunately, with the advent of safe antiviral therapy, specifically acyclovir, HSV disease is treated in the pregnant woman.

From several prospective trials, the major risk to the fetus is maternal primary or initial genital HSV infection.^{127,599} Thus, identification of the woman at risk for primary infection (seronegative for HSV-2 or both HSV-1 and HSV-2) is important. Studies of the discordant serologic status of sexual partners and rates of acquisition of genital HSV-2 infection define this problem.^{127,898} Primary or initial genital infection occurs at rates from 5% to 10% per year.^{130,898} If a pregnant woman experiences initial or primary genital infection in the last trimester of gestation, the likelihood of transmission to the fetus is between 30% and 50%. On the other hand, recurrent maternal infection is associated with a rate of transmission of 3% or less.¹²⁶ These different rates of transmission have direct implications on strategies to prevent neonatal disease or at least ameliorate it if the child is inadvertently delivered through an infected birth canal. In the United States, approximately 1 in 2,000 live births (~2,000 per year) are infected with HSV.

Maternal primary infection before 20 weeks gestation in some women has been associated with spontaneous abortion.⁷⁸⁵ Precise data, indicating the true risk of spontaneous abortion after primary infection during gestation, are not known. However, the contribution of primary maternal genital infection to spontaneous abortion must be weighed above that of a routine rate of fetal loss of approximately 20%. Infection that develops later in gestation has not been associated with the termination of pregnancy.^{395,406,423}

Recurrent infection is the most common form of infection during gestation. Transmission of infection to the fetus is usually related to shedding of virus at the time of delivery. The actual prevalence of viral excretion at delivery is about 0.5% for all women, irrespective of past history¹¹⁹⁷ and perhaps as high as 0.6%.¹²⁵

Several prospective studies have evaluated the frequency and nature of viral shedding in pregnant women with a known history of genital herpes. In a predominantly white, middle-class population, documented recurrent infection occurred in 84% of pregnant women with a history of herpes.¹¹⁹⁷ Asymptomatic viral shedding occurred in at least 12% of the recurrent episodes. Viral shedding from the cervix occurred in 0.56% of symptomatic infections versus 0.66% of asymptomatic infections and higher in some populations (3%),⁴²⁸ as reported in other populations.^{33,110,923} The frequency of recurrences has not been shown to be different from one pregnancy to the next for a given woman.⁴²⁴ The frequency of shedding does not appear to vary by trimester during gestation.^{424,1197} Most infants who develop neonatal disease are born to women who are completely asymptomatic for genital HSV infection and have neither a past history of genital herpes nor a sexual partner reporting a genital vesicular rash.^{1247,1252,1256} These women account for 60% to 80% of all women whose infected children become clinically ill.

animal models provided most data that address the relationship between host defense and disease pathogenesis. Host genetic background, innate immune responses, macrophages, NK cells, specific T-cell subpopulations, specific antibodies, and cytokine responses are important host defenses against HSV infections. However, more recently, human studies have been far more insightful.¹⁰⁸⁹ Local control mechanisms of viral spread aim to neutralize the infectious agent and lead to viral clearance. Following primary HSV infection, the initial, local immunological responses involve both nonspecific defense mechanisms, namely IFN- α/β , activated NK cells, and macrophages, as well as HSV-specific responses, such as CTLs.⁸⁸⁸ The role of T cells has attracted increasing attention, particularly as it relates to vaccine development.^{470,566,615,616,890}

In response to a viral infection, the initial cellular response is synthesis and secretion of type I IFNs (α and β). IFNs induce an antiviral state in infected and surrounding cells. The antiviral activity is modulated in part by IFN-mediated activation of cellular enzymes such as 2'-5' oligoadenylate synthetase (2'-5' AS) and double-stranded RNA-dependent protein kinase, as well as intracellular signaling molecules through the activation of the JAK/STAT kinase pathway. More specific to HSV infection, IFN- α appears to inhibit immediate-early gene expression.²⁵⁸ Thus, the antiviral mechanism directly affects transactivation of the immediate-early responsive element necessary for synthesis of viral proteins.

In addition to antiviral activity, IFNs are potent immunomodulators. As such, they mediate macrophage and NK cell activation, activate CTLs, induce MHC class I and II antigens, stimulate cytokine secretion, and induce local inflammation. IFN- γ may aid in the control of HSV infection. Evidence that $\gamma\delta$ T cells, NK cells, CD4⁺ T cells, and possibly neurons produce IFN- γ and TNF in response to HSV infection in the nervous system has been reported. IFN- γ down-regulates priming of CD4⁺ Th2 cells, which are responsible for inducing Ig isotype B-cell switching from immunoglobulin A (IgA) to IgG, thereby exerting a major effect on humoral immune responses.⁴⁵⁹

NK cells lyse pathogen-infected cells before virus-specific T-cell immunity is generated and constitute first-line defense against infection. *In vitro* and *in vivo* experiments have demonstrated that NK cells protect from HSV challenge in a murine model.⁷⁴⁷ Severe herpetic disease has been correlated with low *in vitro* NK activity in newborns, as well as in a patient lacking NK cells.⁹³ Other mononuclear cells, such as macrophages, are recruited to the site of infection and, upon activation, release immune cell mediators such as TNF and ILs. Macrophages play a major role in mediating antibody-dependent cellular toxicity for viral clearance and antigen presentation.⁶⁷⁹

An important aspect of immune responses to HSV infections is the maturation of DCs at the site of infection. Mobile DCs travel from mucosal or skin areas of infection and prime antigen-specific, naive T cells in draining lymph nodes (DLNs). Studies using HSV-1 footpad infection and fractionating DC subpopulations in the DLN show that classic, CD8 α^+ dermal DCs, rather than specialized epidermal Langerhan's cells (LCs), are able to prime naive CD8⁺ T cells.⁷⁹ In the case of vaginal HSV-2 infection, dermal DCs rather than LCs again seem to be the physiologically active cell population in a similar DLN investigation.¹³¹² LCs are certainly able to present HSV antigens to memory HSV-specific T cells and may participate in primary or recurrent immune reactions. Plasmacytoid dendritic

HOST IMMUNOLOGICAL RESPONSES

Primary Immune Responses

The natural history of HSV infections is influenced by both innate and induced host defense mechanisms. Historically,

cells (pDCs) react to HSV by producing copious amounts of IFN- α .¹⁰⁴⁵ pDCs are recruited to sites of infection, participate in viral clearance, and express relevant TLRs, including TLR 7, 8, and 9—the latter having been shown to recognize HSV.^{689,997} Of interest, a low pDC number or poor pDC reactivity with HSV is associated with severe HSV infection in humans.^{1,249}

As infection progresses, virus-specific immune responses are detected. On days 4 and 5 post infection, HSV-specific CD4⁺ Th1 lymphocytes are detected in genital lymph nodes and in smaller numbers in peripheral blood; they can subsequently be found in the genital mucosa.⁷⁵¹ CD8⁺ responses also occur quite quickly in the mouse⁷⁷¹; relevant human studies have not yet been reported.

Humoral immune responses rapidly follow initial HSV infection. The predominant mucosal antibodies are of the IgA isotype, being secreted by plasma cells. These antibodies can be detected as early as day 3 following infection, peaking within the first 6 weeks after disease onset, and are followed by appearance of IgG1 and IgG3 subclasses of antibodies, which are typically found following viral infections. HSV-specific IgA antibodies are present for at least 6 weeks, gradually decreasing to undetectable levels. Immunoglobulin M (IgM)—secreting B cells have also been detected in secretions of the female genital mucosa.⁷⁷⁷ Shorter periods of viral shedding in women with primary genital herpes have been positively correlated with the presence of secretory IgA in vaginal secretions.⁷⁴⁷ From a systemic perspective, analyses of antibody responses by immunoblot and immunoprecipitation to infected cell polypeptides have been correlated with the development of neutralizing antibodies.^{34,83,84,308,1327} Soon after the onset of infection, antibodies to structural proteins are followed by those directed against gD, gB, ICP4, gE, gG-1 or gG-2, and gC.⁵²³ Both IgM and IgG antibodies can be detected, depending on the time of assessment after infection.

Recurrent Herpes Simplex Virus Infection

Early on, cytokine production was incriminated in the pathogenesis of frequently recurrent genital and labial HSV infection. A decrease in both IFN- γ production and NK cells was reported during the disease prodrome.²⁴¹ With more knowledge, it was learned that HSV-specific CD8⁺ and CD4⁺ T cells persistently infiltrate latently infected trigeminal ganglia in mice and humans.^{543,1189} These cells appear to act via IFN- γ .⁶⁶¹ They have cytolytic activity, but neuron loss is not seen clinically, and inhibitory receptor-ligand pairings can be documented in the ganglia that may modulate their cytotoxic activity.¹¹¹³ In the periphery, HSV-2-specific CD4⁺ and CD8⁺ T cells localize to sites of recurrent HSV-2 infection and to the cervix.^{567,568} Using *in situ* staining, HSV-2-specific CD8 CTL has been shown to persist at the epidermal/dermal junction adjacent to sensory nerve endings.¹³²² Damage to these cell populations in immune-compromised persons may lead to increased HSV replication either centrally or peripherally. In fact, this finding has been incriminated as the basis of failed acyclovir trials on the prevention of person-to-person transmission of infection in individuals with¹³²² HIV-acquired immunodeficiency virus (AIDS) (Medical Research Council [MRC], HIV Prevention Trials Network [HPTN]). Repeated subclinical episodes of HSV excretion may be a source of antigenic stimulation leading to long-term HSV-specific immune memory.⁶⁷⁹ In recurrent HSV-2 infections, NK and HSV-specific CD4⁺ cells are detected earlier than CD8⁺ cells in genital lesions.⁴⁵⁹ CD4⁺

T cells and, more recently, CD8⁺ T cells have been highlighted as major mediators of viral clearance from mucocutaneous lesions in recurrent episodes.^{567,888,889} Low IFN- γ titers in vesicle fluid have been associated with a shorter time to the next recurrence in patients with frequent recurrences. T-cell proliferation is decreased in these patients in comparison to patients with less frequent recurrences.⁶⁷⁹ In as much as the involvement of cytokines has been studied, IFN- γ has been reported to have a role in viral clearance from mucocutaneous sites, whereas altered cytokine production appears to correlate with recurrence.¹⁰⁹²

As with primary HSV infection, a shorter duration of viral shedding occurs in women with recurrent genital herpes who have detectable secretory IgA in vaginal secretions.⁷⁴⁷ IgA, IgG1, and IgG3 antibodies have been found in the sera of all patients with recurrent HSV-2 episodes, whereas IgM and IgG4 antibodies were detected in 70% to 80% of these patients. However, there does not appear to be clear correlation between humoral immune responses and disease prognosis.⁴²⁷

Persistence of Immune Responses

The host's immune responses persist and partially control HSV disease; recurrent episodes are generally less severe and of shorter duration over the years, perhaps owing to progressive enhancement of long-term immunity.⁸¹ Furthermore, some degree of cross-protection exists between HSV-1 and HSV-2, as best evidenced by partial protection of newborns by maternal antibodies.¹²⁵⁰ Finally, HSV-specific T-cell infiltrates are detected in herpetic lesions during early disease resolution.⁸⁸⁸

Studies indicate that persistent cell-mediated immune responses are more important than humoral immune responses in the resolution of HSV disease.⁸⁵ NK cells, macrophages, and T lymphocytes, as well as cytokines such as IFN- α and - γ , IL-2, and IL-12, all have central roles in resolving HSV disease.⁹⁴⁰ HSV-specific CD4⁺ and CD8⁺ cells are detected in lesions from recurrent episodes, indicating their potential role in controlling HSV disease.^{567,888} By contrast, agammaglobulinemic patients do not experience more severe or more frequent herpetic recurrences than the general population.⁵⁹¹ Importantly, several vaccine trials have demonstrated that the presence of neutralizing antibodies to HSV glycoproteins does not provide protection against HSV infection or disease. Although a recent vaccine study suggested benefit for genital HSV-1 infection,⁷⁸ the contribution of HSV-1 to recurrences and acquisition of HSV-2 is significantly less medically important.

Relationship Between Immune Response and Disease

Efforts to precisely incriminate that arm of the host response responsible for disease have not been established. Humoral immunity to HSV infection has been evaluated exhaustively in disease pathogenesis. From a clinical perspective, prior HSV-1 infection has a somewhat protective effect on the acquisition of HSV-2 infection,⁷⁴⁵ albeit controversial. In animal models, polyclonal antibodies have been used to alter disease lethality, particularly in the newborn mouse or to limit progression of both neurologic and ocular disease.^{252,278,533,574,600,730,820,821,927,1049} Monoclonal antibodies to selected specific infected cell polypeptides, especially the envelope glycoproteins gB and gD, confer protection from lethality.^{55,278,927} Importantly, gD2 is a known target of neutralizing antibodies, antibody-dependent

cell-mediated cytotoxicity, and CD4 and CD8 T-cell-mediated responses.^{436,514,756,1307} As a consequence, this antigen has been a prime component of subunit vaccines.

Efforts to correlate the frequency recurrences with immune responses have failed to identify any specific humoral response to specific polypeptides.^{83,85,524} Thus, further efforts have focused, in large part, on cell-mediated immune responses. As noted, lymphocyte blastogenic responses are demonstrable within 4 to 6 weeks after the onset of infection and sometimes as early as 2 weeks.^{233,850,921,974,975,1036,1094,1109} These responses are typically mediated by CD4⁺ T cells. With recurrences, boosts in blastogenic responses occur; however, these responses, as after primary infection, decrease with time. Nonspecific blastogenic responses do not correlate with a history of recurrences. HSV-1 and HSV-2 are cross-reactive in these assays at the whole virus levels, although individual T-cell clonotypic responses can be either type common or type specific.⁵⁶⁴

Lymphokine production has been incriminated in the pathogenesis of frequently recurrent genital and labial HSV infection. Notably, several investigators have recognized a decrease in both IFN- γ production and NK cells during disease prodrome.^{241,835,1034} Nevertheless, there are no reproducible data from selected populations to confirm these observations. The relevance of lymphokine expression in vaccine development can be assessed only in prospective field trials.

Host response of the newborn to HSV must be defined separately from that of older individuals. Immaturity of host defense mechanisms is a cause of the increased severity of some infectious agents in the fetus and the newborn. Factors that must be considered in defining host response of the newborn include the mode of transmission of the agent (viremia vs. mucocutaneous infection without blood-borne spread), time of acquisition of the infection, and the potential of increased virulence of certain strains, although this last point remains purely speculative. Two broad issues are of relevance: protection of the fetus by transplacental antibodies and definition of host responses of the newborn. Transplacentally acquired neutralizing antibodies either prevent or ameliorate infection in exposed newborns, as does antibody-dependent cell-mediated cytotoxicity.^{575,899,1297} Importantly, pre-existing antibodies, indicative of prior infection, significantly decrease the transmission of infection from pregnant women to their offspring,¹²⁵ contributing to the rationale for the development of a HSV vaccine.

Humoral IgG and IgM responses have been well characterized. Infected newborns produce IgM antibodies specific for HSV within the first 3 weeks of infection. These antibodies increase rapidly in titer during the first 2 to 3 months, and they may be detectable for as long as 1 year after infection. The most reactive immunodeterminants are the surface viral glycoproteins, particularly gD. Humoral antibody responses have been studied using contemporary immunoblot technology, and the patterns of response are similar to those encountered in adults with primary infection.^{525,1109} The quantity of neutralizing antibodies is lower in babies with disseminated infection.^{1109,1297}

Cellular immunity has been considered to be important in the host response of the newborn. The T-lymphocyte proliferative response to HSV infections is delayed in newborns compared to older individuals.¹¹⁰⁹ Most infants studied in a recent evaluation had no detectable T-lymphocyte responses to HSV 2 to 4 weeks after the onset of clinical symptoms.^{850,920,1109} The correlation between these delayed responses may be of signifi-

cance in evaluating outcome to neonatal HSV infection. Specifically, if the response to T-lymphocyte antigens in children who have disease localized to the skin, eye, or mouth at the onset of disease is significantly delayed, disease progression may occur at a much higher frequency than babies with a more appropriate response.^{192,1109}

Infected newborns have decreased production of IFN- α in response to HSV when compared to adults with primary HSV infection.¹¹⁰⁹ The importance of the IFN generation on the maturation of host responses, particularly the elicitation of NK-cell responses, remains to be defined.^{131,571} Lymphocytes from infected babies have decreased responses to IFN- γ during the first month of life.^{137,571,1109} In general, the newborn has poorer immune responses than older children and adults. Antibodies plus complement and antibodies mixed with killer lymphocytes, monocytes, macrophages, or polymorphonuclear leukocytes will lyse HSV infected cells *in vitro*.⁹⁷¹ Antibody-dependent cell-mediated cytotoxicity has been demonstrated to be an important component of the development of host immunity to infection.⁵⁷⁰ However, the total population of killer lymphocytes of the newborn seems to be lower than that found in older individuals, and monocytes and macrophages of newborns are not as active as those of adults.^{30,451,572,573,680,1160} These findings are supported by animal model data.

Host Susceptibility

Recent data indicate that a select group of children are prone to develop encephalitis with primary infection and are at risk for recurrent life-threatening HSV infections. These children have been found to have inborn errors of *TLR3*, *TRIF*, *UNC93B1*, or *TRAF3*. These unique studies warrant further elaboration in defining genetic susceptibility to recurrent HSV infections.^{164,993,1309}

CLINICAL MANIFESTATIONS OF DISEASE

HSV disease ranges from the usual case of mild illness, nondiscernible in most individuals, to sporadic, severe, and life-threatening disease in a few infants, children, and adults. Although HSV-1 and HSV-2 are usually transmitted by different routes and involve different areas of the body, there is a great deal of overlap between the epidemiology and clinical manifestations of these two viruses. Historically, primary HSV-1 oropharyngeal infections occurred in the young child (<5 years) and were most often asymptomatic. More recently, HSV-1 infections have become a significant cause of genital herpes as the first manifestation of disease, as is discussed later.¹²⁸⁰ When the oropharynx is involved, the mouth and lips are the most common sites of HSV-1 infections, causing gingivostomatitis; however, any organ can become infected with this virus.

Primary/Recurrent Oropharyngeal Disease

The clinical symptoms of primary HSV-1 infections vary greatly. Infection can be totally asymptomatic or result in combinations of fever, sore throat, ulcerative and vesicular lesions, gingivostomatitis, edema, localized lymphadenopathy, anorexia, and/or malaise. Asymptomatic infection is the rule rather than the exception. The incubation period ranges from 2 to 12 days, with a mean of approximately 4 days.

FIGURE 60.20. Herpes simplex gingivostomatitis.

Symptomatic disease in children is characterized by involvement of the buccal and gingival mucosa¹⁰⁸⁴ (Fig. 60.20). The duration of clinical illness may be from 2 to 3 weeks with fever of 101°F to 104°F. Children with symptomatic primary infection often are unable to swallow liquids because of the significant edema and ulcerative lesions of the mucosal membranes and the associated pain. Lesions within the mouth evolve from vesicles to shallow ulcerations on an erythematous base and then heal slowly. In contrast to cutaneous lesions, intraoral lesions are not associated with the development of scabs. Submandibular lymphadenopathy is common with primary HSV gingivostomatitis but rare with recurrent infections. A clinical distinction should be drawn between intraoral gingival lesions and lip lesions indicative of presumed primary and recurrent infections, respectively. Utilizing PCR detection of viral DNA, evidence of viremia can be documented in approximately one-third of symptomatic patients.⁴²²

With primary HSV infections during adulthood, HSV pharyngitis in association with a mononucleosis syndrome is common. Under such circumstances, ulcerative tonsillar lesions on an erythematous base with associated submandibular

FIGURE 60.22. Recurrent herpes simplex labialis.

lymphadenopathy are common.³⁸⁰ The differential diagnosis of both primary HSV gingivostomatitis and pharyngitis focuses on other mucosal lesions of the oropharynx. These would include herpangina (caused by coxsackieviruses), candidal infections of the mouth, Epstein-Barr virus–induced mononucleosis, lesions induced by chemotherapy or radiation therapy, and Stevens-Johnson syndrome.

The onset of recurrent orolabial lesions is heralded by a prodrome of pain, burning, tingling, or itching, which generally lasts for less than 6 hours and is followed by vesicle formation.¹⁰⁸⁵ The natural history of recurrent herpes labialis is illustrated in Figure 60.21.¹⁰⁸⁴ Vesicles appear most commonly at the vermillion border of the lip and persist in most patients only 48 hours at the longest¹²³⁸ (Fig. 60.22). Vesicles generally number from three to five. The total area of involvement usually is less than 100 mm², and lesions progress to the pustular or ulcerative and crusting stage within 72 to 96 hours. Pain is most severe at the outset and resolves quickly over 96 to 120 hours. Similarly, the loss of virus from lesions decreases

FIGURE 60.21. Herpes simplex labialis natural history.

FIGURE 60.23. Genital herpes simplex virus infection (female).

with progressive healing over 2 to 3 days.^{47,1085} Healing is rapid, generally being complete in 8 to 10 days. The frequency of recurrence varies among individuals.¹⁰⁸⁵ The factors responsible for recurrence in humans are both highly variable and poorly defined but include fever, stress, immunosuppression, and exposure to UV light.^{1028,1040}

Primary/Initial/Recurrent Genital Disease

Symptomatic primary genital infection is usually the most severe. After acquisition of HSV infection at a mucocutaneous site, macules and papules appear, followed by vesicles, pustules, and ulcers. The duration of lesions averages 3 weeks. There are both similarities and differences in the clinical symptomatology between men and women with infection.^{229,231} Furthermore, there appears to be no difference in clinical symptoms associated with primary genital HSV infection attributed to either virus species.

Primary infection is associated with (a) larger quantities of virus replicating in the genital tract ($>10^6$ viral particles per 0.2 mL of inoculum) and (b) a period of viral excretion that may persist for an average of 3 weeks. Systemic complications in men are relatively uncommon; however, aseptic meningitis can develop. Paresthesias and dysesthesias that involve the lower extremities and perineum can result from genital herpetic infection. Primary infections can be associated with fever, dysuria, localized inguinal adenopathy, and malaise in both men and women. The severity of primary infection and its association with complications are statistically higher in women than in men, for unknown reasons.²³¹ Systemic complaints are common in both sexes, approaching 70% of all cases. Extragenital lesions are common.

In women with primary infection, lesions appear on the vulva and are usually bilateral,⁹⁵⁶ as shown in Figure 60.23, with the cervix being invariably involved. The actual frequency of primary cervical infection in the absence of vulvar infection is unknown. Lesions usually are excruciatingly painful, associated with inguinal adenopathy and dysuria, and may involve the vulva, perineum, buttocks, cervix, and/or vagina. A urinary

retention syndrome occurs in 10% to 15% of females, and as many as 25% will develop aseptic meningitis.

In men, primary genital HSV infections are most often associated with vesicular lesions superimposed on an erythematous base, usually appearing on the glans penis or the penile shaft,⁹⁵⁶ as shown in Figure 60.24. The total number of lesions can vary significantly. Extragenital lesions of the thigh, buttocks, and perineum can occur.

Complications of primary genital herpetic infection have included sacral radiculomyelitis, which can lead to urinary retention, neuralgias, and meningoencephalitis.^{152,445,450,1056,1136} Primary perianal and anal HSV-2 infections, as well as associated proctitis, are common in male homosexuals.³⁸⁶ HSV-2 can be isolated from the rectum of heterosexual males and females as well. As with HSV-1 infections, many primary HSV-2 illnesses are subclinical, involving the mouth or the uterine cervix.¹²⁹⁹

Nonprimary but initial genital infection (i.e., occurring in an individual with pre-existing antibody) is less severe

FIGURE 60.24. Genital herpes simplex virus infection (male).

symptomatically and heals more quickly than primary infection. The duration of disease is approximately 2 weeks. The number of lesions, severity of pain, and likelihood of complications are significantly decreased. Pre-existing antibodies to HSV-1 appear to have an ameliorative effect on disease severity of HSV-2^{611,1011,1207} but do not appear to prevent infection.

Recurrent genital herpes is the mildest form of disease. With recurrent genital herpetic infection, a limited number of vesicles, usually three to five, appear on the shaft of the penis of the male or as simply a vulvar irritation in the female.⁵ The duration of disease is approximately 7 to 10 days and parallels that encountered with recurrent HSV labialis. Neurologic or systemic complications are uncommon with recurrent disease; however, paresthesias and dysesthesias can occur.

Some individuals experience their first-episode genital infection years after an asymptomatic or atypical primary infection. In such circumstances, disease can be as severe as true primary infection.

The extent of viral replication is different for recurrent infection as compared with primary infection. Virus is shed for an average of only 2 to 5 days and at lower concentrations ($\sim 10^2$ to 10^3 per 0.2 mL of inoculum in tissue culture systems). Recurrent genital infection in both men and women is characterized by prodrome (which is a useful marker for therapeutic trials)⁶⁸⁷ and localized irritation.

The major problem with recurrent genital HSV infection is the frequency of recurrences, which varies from one individual to the next. Anecdotally, the severity of primary infection correlates directly with the frequency of recurrences—that is, the more severe the primary infection, the more likely and frequent the recurrences. Notably, virtually all patients will suffer from recurrences, whether symptomatic or asymptomatic; however, it does vary by virus type. For those individuals with genital HSV caused by HSV-1, the probability of recurrences is significantly less and, in some patients, virtually not at all. On the other hand, HSV-2 genital infections are prone to recur. One-third of patients are estimated to have recurrences in excess of eight or nine times per year, one-third will have two to three per year, and the remaining one-third will have four to seven.²³¹ Obviously, with recurrences, either symptomatic or asymptomatic, transmission of infection to sexual partners can occur with intimate contact. HSV DNA can be detected by PCR^{218,1203} three to five times more frequently than the isolation of virus. Recent data suggest much more frequent intermittent shedding of reactivation with episodes lasting only a few hours. These data provide a rationale for ongoing transmission of infection.

Neonatal Herpes Simplex Virus Infection

Incidence and Transmission of Newborn Infection

The estimated incidence of neonatal HSV infection is approximately 1 in 3,000 to 1 in 5,000 deliveries per year.⁵⁵² Neonatal HSV infection occurs far less frequently than genital HSV infections in the adult childbearing population. At least four factors influence transmission of infection from mother to fetus. First, the risk of transmission with maternal primary or first-episode genital infection during the third trimester is 30% to 50% as compared with 3% or less with recurrent infection.^{125,127} In part, this reflects prolonged viral excretion during the third trimester of gestation as well as an inadequate

transplacental antibody transfer. Second, transplacental maternal neutralizing and antibody-dependent cell-mediated cytotoxic antibodies appear to have at least an ameliorative effect on acquisition of infection and disease presentation, as noted earlier.^{38,786,899,1296,1297} Third, prolonged rupture of membranes (>6 hours) increases the risk of acquisition of virus. Fourth, certain forms of medical intervention in the labor and delivery suites may increase the risk of neonatal HSV infection, including the use of fetal scalp monitors.^{538,848}

Acquisition and Presentation of Infection

Infection of the newborn can be acquired *in utero* (congenital), intrapartum, or postnatally. The mother is the most common source of infection for the first two of these routes of transmission. The reader is referred to a more detailed treatise on this disease.⁴⁰⁶

CONGENITAL INFECTION

In utero infection can occur as a consequence of either transplacental or ascending infection.^{58,482} The incidence has been estimated to be 1 in 200,000 deliveries.⁵⁸

Placental necrosis and inclusions in the trophoblast can occur.^{357,361,1271} Intrauterine infection is characterized by the triad of skin vesicles or skin scarring, eye disease (chorioretinitis or microphthalmia), and the far more severe manifestations of microcephaly or hydranencephaly.

INTRAPARTUM INFECTION

The most common route of infection is that of intrapartum contact of the fetus with infected maternal genital secretions. Likely, 75% to 80% of infected babies acquire HSV infection by this route. Babies who are infected intrapartum or postnatally with HSV infection are classified as having (a) disease localized to the skin, eye, and mouth; (b) encephalitis with or without skin involvement; and (c) disseminated infection that involves multiple organs, including the CNS, lung, liver, adrenals, skin, eye, and/or mouth.^{551,1254}

Babies with the worst prognosis both for mortality and morbidity have disseminated infection.¹²⁴⁷ These children are usually referred to tertiary care centers for therapy at 9 to 11 days of age; however, signs of infection usually begin an average of 4 to 5 days earlier. The principal afflicted organs are the liver and adrenals; however, there can be involvement with multiple other organs, including the larynx, trachea, lungs, esophagus, stomach, lower gastrointestinal tract, spleen, kidneys, pancreas, and heart. Constitutional signs and symptoms include irritability, seizures, respiratory distress, jaundice, bleeding diatheses, shock, and, frequently, the characteristic vesicular exanthem, which is often considered pathognomonic for infection. Encephalitis appears to be a common component of this form of infection, occurring in about 60% to 75% of children with disseminated infection. More than 20% of these children do not develop skin vesicles during the course of their illness.^{35,1247} Mortality in the absence of therapy exceeds 80%; all but a few survivors are impaired. The most common cause of death in babies with disseminated disease is either HSV pneumonitis or disseminated intravascular coagulopathy.

Babies with infection of the CNS alone or in combination with disseminated disease present with the findings indicative of encephalitis. Overall, nearly 75% of babies with disseminated disease have evidence of acute brain infection. Clinical

manifestations of either encephalitis (alone or in association with disseminated disease) include seizures (both focal and generalized), lethargy, irritability, tremors, poor feeding, temperature instability, bulging fontanelles, and pyramidal tract signs. Whereas babies with disseminated infection often have skin vesicles in association with brain infection, the same is not true for the baby with encephalitis alone. This latter group of children may only have skin vesicles in approximately 60% of cases at any time in the disease course.^{35,406,1110,1247} Death occurs in 50% of babies with localized CNS disease who are not treated and is usually related to brain system involvement. With rare exceptions, survivors are left with severe neurologic impairment.^{1239,1248}

The long-term prognosis, after either disseminated infection or encephalitis, is poor in the absence of antiviral therapy. As many as 50% of surviving children have some degree of psychomotor retardation, often in association with microcephaly, hydranencephaly, porencephalic cysts, spasticity, blindness, chorioretinitis, or learning disabilities. Recent data suggest that CNS damage can be progressive after initial clearance of the viral infection, as predicated upon long-term antiviral suppressive data administered to babies with encephalitis.⁵⁵⁴

Subclinical infection of the CNS has been detected in babies with disease apparently localized to the skin, eye, and mouth. These children had normal cerebrospinal fluid assessments but PCR-detectable HSV DNA at the onset of disease.⁵⁵⁰ Subsequently, a subset of these children developed neurologic impairment.

Importantly, in as many as 40% of children with disease localized to the CNS (e.g., the 2- to 3-week-old baby with cells and protein in the cerebrospinal fluid), skin vesicles (the classic sign of disease) are not present. For the neonate with cerebrospinal fluid findings indicative of infection, HSV must be

considered along with other bacterial pathogens (e.g., group B *streptococcus*, *E. coli*). A reasonable diagnostic approach—if all antigen and Gram stain studies and PCR evaluations are negative—would be serial cerebrospinal fluid examinations to document progression in protein and mononuclear cell counts.

Infection localized to the skin, eye, and/or mouth is associated with lower mortality; however, significant morbidity can occur. When infection is localized to the skin, the presence of discrete vesicles remains the hallmark of disease. With time, the rash can progress to involve other areas of the body as well, particularly if viremia occurs. Vesicles occur in 90% of children with skin, eye, or mouth infection. These children present at about 10 to 11 days of life. Babies with skin lesions invariably will experience recurrences over the first 6 months (and longer) of life, regardless of whether therapy was administered. Although death is not associated with disease localized to the skin, eye, and/or mouth, approximately 30% of these children eventually develop evidence of neurologic impairment.^{1239,1248,1252} The skin vesicles, as shown in Figure 60.25, usually erupt from an erythematous base and are usually 1 to 2 mm in diameter. Other manifestations of skin lesions have included a zosteriform eruption.⁷⁷⁹

Infections involving the eye may manifest as keratoconjunctivitis or, later, as chorioretinitis. The eye can be the only site of HSV involvement in the newborn.¹²⁴⁸ These children present with keratoconjunctivitis or, surprisingly, evidence of microphthalmia and retinal dysplasia.

POSTNATAL ACQUISITION

Lastly, postnatal acquisition of HSV-1 accounts for about 10% of cases.^{288,303,344,417,545,647,653,786,1111} The presentation is similar to that described previously and usually is the consequence of family contact with the newborn.

FIGURE 60.25. Vesicular rash of neonatal herpes simplex virus infection.

FIGURE 60.26. Dendritic lesions of herpes simplex keratoconjunctivitis.

Herpes Simplex Keratoconjunctivitis

Viral infections of the eye are usually caused by HSV-1 beyond the newborn age.^{92,834,1024} Approximately 300,000 cases of HSV infections of the eye are diagnosed yearly in the United States. These infections are second only to trauma as the cause of corneal blindness in the United States. Primary herpetic keratoconjunctivitis is associated with either unilateral or bilateral conjunctivitis, which can be follicular in nature, followed soon thereafter by preauricular adenopathy. HSV infection of the eye is also associated with photophobia, tearing, eyelid edema, and chemosis, accompanied by the pathognomonic findings of branching dendritic lesions⁹⁵⁶ (Fig. 60.26). Less commonly, with progressive disease, the infection is associated with a geographic ulcer of the cornea⁹⁵⁶ (Fig. 60.27). Healing of the cornea can take as long as 1 month, even with appropriate antiviral therapy.

Recurrent HSV infections of the eye are common. Recurrences parallel that which was described for herpes labialis. Most frequently, recurrences are unilateral in involvement,

FIGURE 60.27. Geographic corneal ulcer caused by herpes simplex virus infection.

although a small percentage of cases involve both eyes. Characteristically, either dendritic ulceration or stromal involvement occurs. Visual acuity is decreased in the presence of the ulcers; with progressive stromal involvement, opacification of the cornea may occur. Repeated recurrences may last for weeks or even months after appropriate antiviral therapy. The route and pathogenesis of infection remain unknown. Progressive disease results in visual loss and even rupture of the globe.

Skin Infections

Skin infections caused by HSV generally manifest as eczema herpeticum in patients with underlying atopic dermatitis, occurring in 1% to 2%.^{310,903,1135,1234} The lesions can either be localized, resembling herpes zoster with a dermatomal distribution, or disseminated. The latter occurs commonly in Kaposi's varicella-like eruption.⁹⁷³ HSV infections of the digits, known as herpetic whitlow, have been reported and are particularly common among medical and dental personnel.⁹⁶⁹ The estimated incidence is 2.4 cases per 100,000 individuals per year, and the cause may be HSV-1 or HSV-2.³⁷⁷

In addition to individuals with atopic disease, patients with skin abrasions or burns appear particularly susceptible to HSV-1 or HSV-2 infections, and some may develop disseminated infection.³³⁶ Disseminated HSV infections have been also reported among wrestlers (herpes gladiatorum).¹²³⁵ Other skin disorders associated with extensive cutaneous lesions include Darier disease and Sezary syndrome.^{431,452} Localized recurrences followed by a second episode of dissemination have been reported.⁸³² HSV infections of either type can trigger erythema multiforme.¹²³³ The presence of HSV DNA in skin lesions of erythema multiforme is as high as 80%.

Infections of the Immunocompromised Host

Patients compromised by immunosuppressive therapy, underlying disease, or malnutrition are at increased risk for severe HSV infections. Renal, hepatic, bone marrow, and cardiac recipients are all at particular risk for increased severity of transplant HSV infection.^{773,851,1251} An example of cutaneous dissemination after shaving, in a renal transplant recipient, is shown in Figure 60.28.⁹⁵⁶ In organ transplant recipients, the presence or quantity of HSV antibodies before treatment predicts the individual at greatest risk for recurrence.⁸⁵² Acquisition of HSV infection from a transplanted organ (kidney) has been reported.³⁰¹ These patients may develop progressive disease involving the respiratory tract, esophagus, or even the gastrointestinal tract.^{578,764} The severe nature of progressive disease in these patients appears to be directly related to the type of immunosuppressive therapy.⁹¹⁴ Esophagitis is a common occurrence in the immunocompromised host and can be caused by HSV, CMV, or *Candida albicans*. Notably, acyclovir-resistant HSV disease can occur in the immunocompromised host and can be progressive. Reactivation of latent HSV infections in these patients can occur at multiple sites, and healing in these patients with severe progressive disease occurs over an average of 6 weeks.¹²⁵⁵

Since the first reports of AIDS, the severity of HSV clinical disease in these severely immunocompromised hosts was noted.^{704,1208} Herpetic disease, even more exaggerated than in the cancer patient (e.g., proctitis), has been reported and is an essential target for antiviral therapy. Disease severity correlates with CD4 count and the probability of developing resistance to antiviral therapy. As noted earlier, genital ulcerative disease,

FIGURE 60.28. Cutaneous dissemination of herpes simplex virus infection in an immunosuppressed host.

including HSV infection, increases the risk for acquisition of HIV infection.^{69,1203} Furthermore, despite highly active antiretroviral therapy, HSV recurrences are more common than in the normal host.⁸⁹¹ Asymptomatic excretion of HSV can occur even in the immunocompromised host, as is best exemplified in HIV-infected individuals.^{1004,1005,1207}

Infections of the Central Nervous System

Herpes simplex encephalitis is one of the most devastating of all HSV infections⁹⁵⁶ (Fig. 60.29), being the most common

cause of sporadic, fatal encephalitis in this country.^{830,1244} The incidence of severe hemorrhagic focal encephalitis is approximately 1 in 250,000 individuals per year, for a national annualized rate of approximately 1,250 cases in the United States.

HSV encephalitis is primarily a focal encephalitis associated with fever, altered consciousness, bizarre behavior, disordered mentation, and localized neurologic findings. These clinical signs and symptoms generally are associated with evidence of localized temporal lobe disease, as demonstrated by neurodiagnostic procedures.^{1253,1254} There are no pathognomonic findings

FIGURE 60.29. Coronal section of brain from a patient with herpes simplex encephalitis.

for herpes simplex encephalitis; however, a progressively deteriorating level of consciousness, fever, an abnormal cerebrospinal fluid formula, and focal neurologic findings in the absence of other causes should make this disease highly suspect. Other diagnostic evaluations should be initiated immediately because other treatable diseases mimic HSV encephalitis.¹²⁴⁵ Mortality in untreated patients is in excess of 70%, and only 2.5% of all patients return to normal neurologic function.

Neurodiagnostic procedures used in the evaluation of patients with suspect HSV encephalitis include cerebrospinal fluid examination; electroencephalogram; and one or more scanning procedures such as technetium, computed tomography, or a magnetic resonance image scan. Characteristic abnormalities of the cerebrospinal fluid include elevated levels of cells (usually mononuclear) and protein. Red blood cells are found in most (but not all) cerebrospinal fluids obtained from patients with HSV encephalitis. The electroencephalogram generally localizes spike and slow-wave activity to the temporal lobe. A burst suppression pattern is considered characteristic of HSV encephalitis. Imaging will allow for localization of disease to the temporal lobe. Early after onset, only evidence of edema is detectable, if at all. This finding is followed by evidence of hemorrhage and a midline shift in the cortical structures.

PCR detection of HSV DNA in the cerebrospinal fluid has become the diagnostic of choice; however, it must be performed by a qualified laboratory.⁶¹⁸ Serologic assessments of serum or cerebrospinal fluid are not helpful early in the disease course when therapeutic decisions are mandatory.⁷⁸⁹

Other Neurologic Syndromes

In addition to encephalitis, HSV can involve nearly all anatomic areas of the nervous system, including meningitis, myelitis, and radiculitis, among others.²³⁷ Aseptic meningitis is a common occurrence in individuals with primary genital HSV infections. Recurrent aseptic meningitis (Mollaret syndrome) will occur in patients with genital herpes.¹¹⁶⁶ The relationship between HSV infections of the brain and chronic degenerative disease, psychiatric disorders, or Bell palsy requires further definition.^{64,223}

Other Forms of Infection

Other forms of infection are noted briefly. HSV was isolated from the respiratory tract of adults with adult respiratory distress syndrome and acute onset bronchospasm.¹¹⁶⁵ Both were associated with increased mortality and morbidity. In addition, HSV has been associated with Bell palsy.⁷⁷⁵

DIAGNOSIS

The appropriate use of laboratory tools is essential if a diagnosis of HSV infection is to be achieved.²³⁰ Virus isolation is a definitive diagnostic method; however, PCR detection of viral DNA has gained increased acceptance even for routine skin infections, replacing culture in most laboratories. If a culture is obtained, skin vesicles/lesions should be swabbed/scraped and transferred in appropriate virus transport media to a diagnostic virology laboratory. In addition to skin vesicles, other sites from which virus may be isolated include the cerebrospinal fluid,

stool, urine, throat, nasopharynx, and conjunctivae. Clinical specimens should be shipped on ice for inoculation into cell culture systems (e.g., foreskin fibroblasts, Vero cells) that are appropriate for the demonstration of the cytopathic effects characteristic of HSV replication.¹⁰¹⁵ Cytopathic effect tends to develop within 24 to 48 hours after inoculation of specimens containing infectious virus. The shipping and processing of specimens should be expedited.

The advantage of cell culture is the ability to obtain a virus isolate for further testing (e.g., resistance or typing). Typing of an HSV isolate may be accomplished by one of several techniques, which may not be routinely available. Because outcome with treatment does not appear to be related to the virus type, identification is only of epidemiologic and pathogenetic importance and, therefore, not usually necessary.

Every effort should be made to confirm infection by viral isolation or PCR detection of viral DNA. Today, such efforts are both reasonable and the expected standard of care. Cytopathologic detection of evidence of infection is less rewarding. These methods have a sensitivity of only approximately 60% to 70% in babies, and slightly higher in adults, and therefore should not be the sole diagnostic determinant of infection.^{611,788} Cellular material obtained by scraping the periphery of the base of lesions should be smeared on a glass slide and promptly fixed in cold ethanol. The slide can be stained according to the methods of Papanicolaou, Giemsa, or Wright before examination by a trained cytologist. The demonstration of intranuclear inclusions and multinucleated giant cells are indicative, but not diagnostic, of HSV infection. Electron microscopic assays have limited use.⁶²⁷

Serologic diagnosis of HSV infection is clinically valuable in the counseling of patients regarding genital herpes provided that the assays are type specific. This is especially the case with the development of very sensitive and specific assays that distinguish HSV-1 gG-specific antibodies from those of HSV-2 gG-specific antibodies.¹²⁰⁵ Therapeutic decisions cannot await the results of serologic studies. Several commercial and Food and Drug Administration (FDA)-approved assays are available.

The development of PCR has revolutionized the diagnosis of HSV infections and also has allowed for detailed studies of disease pathogenesis. The experience with PCR indicates that it is the most useful tool for diagnosis of HSV encephalitis^{22,42,43,266,472,555,556,902,972,1159} as well as skin lesions—either orolabial or genital. Using primers from an HSV DNA sequence that was common to both HSV-1 and HSV-2 (either the gB or DNA polymerase genes), HSV DNA can be detected in the cerebrospinal fluid of patients undergoing brain biopsies for HSV encephalitis with a sensitivity of more than 95% and a specificity that approaches 100%.⁶¹⁸ False-negative assessments can be found when there is contamination of hemoglobin in the cerebrospinal fluid, when inhibitors are present, or very early in the course of disease.⁶¹⁸ PCR evaluation of cerebrospinal fluid can be used to follow therapeutic outcome in patients with HSV encephalitis. Persistence of HSV DNA in the cerebrospinal fluid of newborns with HSV encephalitis at the completion of antiviral therapy predicts poor neurologic outcome.⁵⁵⁶ PCR is being used to detect HSV DNA in lesions because it has improved sensitivity and specificity.^{219,220,421,1203} As the cost of PCR determinations decreases, an added benefit will be realized.

PREVENTION AND CONTROL OF HERPES SIMPLEX VIRUS INFECTIONS

Genital Herpes Simplex Virus Infections

Because of the increased awareness of genital herpes and neonatal herpes and its association with increased risk of acquisition of HIV, every effort should be made to prevent HSV-2 infections. Until a vaccine is proven efficacious, educational efforts must be developed for adolescents and those at greatest risk. The use of condoms should be promoted, as use significantly decreases the probability of acquiring genital HSV infection. Condoms are more effective in the prevention of infection of females than males.^{163,620,1204} Valacyclovir has been demonstrated to decrease but not totally prevent person-to-person transmission of genital herpes in discordant couples.²³⁴

Prevention of Neonatal Herpes Simplex Virus Infection

Surgical abdominal delivery is associated with the decreased transmission of infection when membranes are ruptured less than 4 hours; however, cesarean section has not been proven efficacious when membranes are ruptured for longer periods of time.¹²⁷

For women with a past history of genital HSV infection, some obstetricians prescribe an antiviral medication during the last 4 weeks of gestation, recognizing a decreased probability of virus excretion.²⁵ However, recent data indicate that despite maternal compliance, maternal transmission can still occur, resulting in severe neonatal HSV disease.⁸⁷⁷

For babies born to mothers with known primary infection during the third trimester of gestation, the American Academy of Pediatrics Red Book Committee recommends 10 days of high-dose intravenous acyclovir therapy followed by careful serial medical assessment.¹⁹ If a child is born through a known infected birth canal, surface cultures and careful follow-up are in order. Should the cultures become positive or the child ill, further evaluation (i.e., cerebrospinal fluid and blood assessment by PCR) are indicated with therapy initiated until a diagnosis is either confirmed or excluded.

At the time of presentation to the labor and delivery suite, a careful vaginal examination is of paramount importance. Although visualization of the cervix is often difficult, speculum examination for documentation of recurrent lesions is extremely important and should be attempted in all women, because it will guide management of the newborn (see later discussion).

Hospital Staff

At many institutions, a policy that requires transfer or medical leave for nursery personnel who have a labial HSV infection is impractical and causes an excessive burden in those attempting to provide adequate care. Temporary removal of personnel who have cold sores is advocated for some clinical services. Education regarding the risk of transmission of virus and the importance of hand washing when lesions are present should be repeatedly emphasized to healthcare workers. In addition, hospital personnel should wear masks when active lesions are present.

Prevention of Other Herpes Simplex Virus Infections

At the present time, the only mechanism for prevention of mucocutaneous HSV infection is to avoid contact with

infected secretions. There are no proven effective postexposure antiviral therapies or vaccines.

VACCINE DEVELOPMENT

Vaccination remains the ideal method for prevention of viral disease; however, prevention of HSV disease introduces unique problems because of recurrences in the presence of humoral and cell-mediated immune responses. Nevertheless, protection from life-threatening disease can be achieved in animal models with avirulent, inactivated, or subunit glycoprotein vaccines, each of which has unique differences. Excellent reviews summarize HSV vaccine development.^{298,515,1089,1090,1246}

Human HSV Vaccine Development

An important consideration for human HSV vaccines is the definition of expectations, warranting a distinction between infection and disease. From animal data, disease can be ameliorated if not prevented; however, infection still occurs. Similarly, the potential of altering the immune response to change the pattern of recurrences in previously infected individuals is unlikely. Thus, in human studies, a goal is to prevent disease, although it is highly unlikely that infection will be altered. Early investigations provide important insights into these expectations according to candidate vaccine: (a) wild-type virus, (b) inactivated or killed virus, (c) subunit vaccines, and (d) live vaccines.

Wild-type Virus Vaccines

Numerous investigators attempted to either prevent or alter the pattern of recurrences by inoculation of (a) autologous virus, (b) virus from another infected individual, or (c) virus recovered from an experimentally infected rabbit. In some cases, inoculation led to recurrences of latent infection.^{99,625} These live viruses were subsequently abandoned because many patients failed to develop lesions at the site of inoculation; therefore, it was concluded that the virus did not produce an “adequate take”,^{90,121,346} as compared to smallpox immunization.

Inactivated (or Killed) Virus Vaccines

Killed viruses were used as vaccines in various animal model systems, often with good results, as reviewed elsewhere.⁷³⁸ The initial inactivated vaccines were made from phenol-treated tissues obtained from infected animals.^{90,121,346} Because of the potential for demyelination after the administration of animal proteins, these vaccines attracted little biomedical attention. UV light inactivation of purified virus derived from tissue culture experiments provided greater impetus for the vaccine field. As reviewed,⁷³⁸ viral antigens obtained from various cell cultures were inactivated either by formalin, UV light, or heat and used administered to thousands of patients.¹²⁴⁰ Although decreased recurrences were reported in as many as 60% to 80% of patients,^{302,794} no controls were used.

Several important observations were made from these studies. First, despite repeated inoculations, antibody titers (as measured by neutralization or complement fixation) remained unchanged in most patients^{132,442,929} or demonstrated only slight increases.^{1072,1196} Second, although few side effects were reported, some authors noted concern that in patients with keratitis, autoimmune phenomena might make the herpetic

disease worse.^{640,1014,1073} Lastly, the need for placebo-controlled observations is imperative.

Subunit Vaccines

Subunit vaccines evolved from attempts to remove viral and cellular DNA, to enhance antigenic concentration and induce stronger immune responses, and, finally, to exclude any possibility of contamination with residual live virus. The immunogenicity of envelope glycoproteins was demonstrated in animals.^{154,155,746,1055} Generally, the subunit vaccines elicited some protection, as evidenced by reduction of morbidity and mortality in the immunized animals. However, the predictability of these models for human studies is disappointing. Furthermore, several injections are required to induce protection, and they must also include adjuvant. Protection in the rodent is significantly easier than in nonhuman primates. Vaccination of primates, specifically rhesus monkeys,¹⁵³ chimpanzees,^{153,154} and *Cebus* monkeys,⁴⁴⁹ induces neutralizing antibodies, which can lead to an amnestic response after subsequent injection months later.

Subunit vaccines have failed in human experiments despite initial promising results. Both HSV-1 and HSV-2 antigens have been prepared in human diploid cells and chicken embryo fibroblasts. The first extensive and thoughtful vaccine experience was reported for individuals receiving the Merck⁴⁴⁹ envelope subunit vaccine.^{37,1306} In uninfected sexual partners of patients known to have genital herpes, the number of individuals developing HSV infection was nearly equal for both placebo and vaccine recipients, indicating that the vaccine was not effective.

Further extensive studies have been completed with two gB and/or gD recombinant vaccines in humans. Initially, a gD-2 construct (30 μ g or 100 μ g with alum) was administered to 24 human volunteers to determine reactogenicity and immunogenicity. These studies demonstrated an increase in the geometric mean neutralizing antibody titer to gD-2; however, lymphocyte blastogenic responses were inconsistent.¹¹⁰⁴ Subsequently, gD-2 combined with a lipophilic muramyl tripeptide was shown to afford a high level of protection from HSV disease in animal models,^{138,992} although this adjuvant was abandoned because of reactogenicity. An important observation from these studies is that the quantity of neutralizing antibodies elicited by immunization and the total HSV antibody titer (as measured by enzyme-linked immunosorbent assay [ELISA]) were higher after vaccination than after natural infection.¹⁰⁹¹

The next series of experiments used alum and gD-2, demonstrating immune responses similar to natural infection¹¹⁰⁴ with the suggestion of decreased recurrent genital herpes.¹²⁴² A controlled clinical trial using gD-2 and gB-2 in a squalene oil and water emulsion (Chiron) failed to demonstrate efficacy for prevention of either infection or disease.²³²

A second candidate vaccine consisting of gD-2 with an alum and monophosphoryl lipid A adjuvant (GlaxoSmith-Kline) was shown to induce titers of HSV gD-specific antibody that were higher than those observed in patients who had sexually acquired genital HSV-2 infection.¹⁰⁹³ In these studies, women who were seronegative for both HSV-1 and HSV-2 were significantly protected from disease (72% efficacy; $p = 0.01$ – 0.02), and there was a trend toward protection against infection (43% efficacy; $p = 0.06$ – 0.07). However, in individuals seropositive for HSV-1, irrespective of sex, and seronegative

men, no significant clinical benefit could be demonstrated. Thus, this genital herpes vaccine (gD-Alum/MPL) was effective in preventing HSV-1 or HSV-2 genital herpes disease in a subset of volunteers—that is, women who were HSV-1 and HSV-2 seronegative (HSV1–/2–) prior to vaccination. However, these studies were neither designed nor powered to assess efficacy exclusively in HSV1–/2– women and therefore did not meet their primary endpoints of overall efficacy. The vaccine had no effect in women who had pre-existing antibodies to HSV-1 or men regardless of their serologic status. A large placebo-controlled study to verify these results has just been completed. The vaccine showed only 20% efficacy in preventing genital herpes disease overall (the primary endpoint) but did show 58% efficacy for preventing HSV-1 genital disease.⁷⁸ The vaccine showed only 22% protection from HSV infection overall but 35% efficacy for preventing HSV-1 infection. Notably, rates of HSV shedding were higher in the vaccine than the placebo group. Both of these subunit vaccines required administration on three occasions.

The difference in response to these two vaccines warrants comment. The Chiron gB-2 and gD-2 vaccine had an adjuvant that induced Th2 responses, whereas the later GlaxoSmith-Kline vaccine induced Th1 responses.

Live Virus Vaccines

For decades, live virus vaccines have been considered most likely to provide a high level of protection as occurs with measles, mumps, and rubella. Live viral vaccines replicate in the recipient, and the resulting immunity should both mimic natural host responses and be longer lasting. Moreover, these vaccines usually require smaller quantities of antigen and, therefore, should be more economical. Several approaches to live virus vaccines have been attempted, including HSV mutants, heterologous herpesviruses, antigens expressed in non-HSV viral vectors, and genetically engineered viruses.

GENETICALLY ENGINEERED HERPES SIMPLEX VIRUS VACCINES

Current technology allows the construction of recombinant HSV as prototype vaccines.^{739,954} These vaccines were engineered with the objectives that they should be attenuated so as not to cause primary disease or to reactivate; able to protect against HSV-1 or HSV-2 disease; provide biomarkers that distinguish vaccine from wild-type infection; and, potentially, serve as vectors to express immunogens of other human pathogens. Notably, there is overlap between engineered vaccine candidates and HSV constructs that are used for gene therapy (see later discussion).

The initial construction of candidate vaccines was based on the use of HSV-1. An engineered HSV was constructed that deleted the viral *TK* gene and the junction region of the U_L and U_S segments in order to excise some of the genetic loci responsible for neurovirulence as well as to create convenient sites and space within the genome for insertion of other genes. An HSV-2 DNA fragment encoding the HSV-2 glycoproteins D, G, and I was inserted in place of the internal inverted repeat. The purpose of the HSV-2 genes was to broaden the spectrum of the immune response and to create a chimeric pattern of antibody specificities. The resulting recombinant, designated as R7017, was further altered by insertion of the *TK* gene next to the HSV-2 DNA fragment (R7020). Because this virus expresses TK, it is susceptible to antiviral chemotherapy with

acyclovir. When analyzed by restriction enzyme digestion, the DNA of the recombinants has a unique pattern that facilitates their unambiguous identification.

When evaluated in rodent models, the two constructs were considerably attenuated in pathogenicity and ability to establish latency and were capable of inducing protective immune responses. The recombinants did not regain virulence on passage, nor did they change DNA restriction enzyme cleavage patterns when subjected to serial passages in the mouse brain.⁷⁴⁰ These results were corroborated by studies in owl monkeys (*Aotus trivirgatus*). Although 100 pfu of wild-type virus administered by peripheral routes was fatal to the monkeys, recombinants given by various routes in amounts at least 10⁵-fold greater were innocuous or produced mild infections, even in the presence of immunosuppression by total lymphoid irradiation.⁷⁴⁰ When R7020 was administered to humans to determine reactogenicity, immune responses were elicited¹⁴³; however, R7020 was not effective at the relatively low doses tested at that time.

The application of these principles to HSV-2 constructs was undertaken and assessed in animal models. The $\gamma_134.5$ gene of HSV-1 was proven to be a mediator of CNS replication, providing a potential vaccine construct upon deletion.¹⁹⁴ Furthermore, deletions of $\gamma_134.5$ significantly decrease the ability of this construct to establish latency.

One promising approach to an HSV vaccine is using replication-defective viruses.²⁹⁷ Although first studied over a decade ago,^{767,805} a current construct deletes U_L5 and U_L29 in HSV-2 to generate the dl5-29 vaccine candidate. Importantly, this vaccine candidate was compared to a gD-2 subunit vaccine in Freund's adjuvant. Significant protection was induced along with high titers of neutralizing antibodies and CD8⁺ T cells.^{299,468,469} This vaccine candidate is targeted for human trials in the near future.

A vaccine deleted for the *gH* gene was studied in a phase II trial in the United Kingdom. This vaccine, known as the HSV-DISC vaccine, undergoes a single cycle of replication. Because gH is deleted, no further replication is possible. The results of this phase II study failed to demonstrate effectiveness in reducing reactivation and disease in persons with recurrent HSV-2.²⁵⁴ An HSV-2 vaccine deleted for several genes involved in immune evasion (ImmunoVEX HSV-2) is in phase I clinical trials.

VECTORED GENE EXPRESSION AND OTHER APPROACHES

Vaccinia virus has been used as a vector for delivering antigens to animals or humans.¹⁰⁶² The principle of inserting foreign genes into a vaccinia vector was exploited for the expression of the gD and gB genes of HSV.⁸³⁹ Because of concern for the development of adverse effects to the vaccine (e.g., vaccinia gangrenosum and disseminated vaccinia), interest in this approach is virtually nonexistent. Furthermore, immune memory in individuals who have previously received vaccinia may prevent recognition of any foreign gene insert.

Adenoviruses have also been proposed as expression vectors on the grounds that they might be safer than vaccinia.⁷²⁵ Animal models show good efficacy when adenovirus expressing gD are administered.¹³¹³ Newer adenovirus platforms have been found in the HIV research field to stimulate strong CD8 responses to the inserted foreign gene,³⁰⁰ rendering this platform attractive for HSV. The varicella zoster virus vaccine strain has been engineered to express HSV glycoproteins. Two

of these constructs have been shown to afford animals protection against experimental HSV-2 genital herpes.^{438,439}

Other approaches being tested include plasmid DNAs encoding HSV genes and HSV-2 peptides complexed with heat shock proteins.

Summary

HSV vaccine development remains a high priority. Current approaches have relied upon prevention of infection as an endpoint of efficacy. Future studies will need to consider the impact of vaccines on amelioration of disease and rely on novel new constructs. As noted earlier, the most advanced at this time is a construct that deletes U_L5 and U_L29 in HSV-2 to generate the dl5-29 vaccine candidate. One such construct will consider the utilization of immunologically dominant T-cell epitopes as a means to improve immune responses.

ONCOLYTIC HERPES SIMPLEX VIRUS THERAPY

Genetically engineered HSVs have mainly been assessed for the treatment of human glioblastoma multiforme. These constructs have included mutations in the viral genes for TK, DNA polymerase, ribonucleotide reductase, and $\gamma_134.5$ ^{118,174,504,532,712,718,754} and have been identified as HF10, HSV1716, NV1020, G207, G47 Δ , OncoVEX^{GM-CSF}, rRp450, M032, and C134.^{166,654,697,739,755,813} Although virtually any alteration of HSV ameliorates neurovirulence, only the deletions in the $\gamma_134.5$ gene consistently demonstrate safety and efficacy in animal models. Tumorcidal effects *in vitro* and *in vivo* in multiple glioma models (mouse, rat, and human glioma cell lines; human glioma explants) are demonstrable. *In vivo* models include tumor reduction in subrenal capsule and flank subcutaneous implants but, more importantly, increased survival and some tumor cures in intracranial implant models. These effects are reproducible *in vivo* for both immune-deficient animals (nude, *scid* mice)^{174,712,718,754} as well as immune-competent models (rats and mice).^{117,504,532,753}

Animal Model Studies

Studies in animal models of gliomas of various constructs of HSV (engineered viruses deleted in $\gamma_134.5$) have been performed. These studies demonstrate the following principles: (a) the time course of infection (quantitative virology and PCR) represents impaired replication with limited spread of virus across the brain using marker genes (*lacZ* under an ICP6 promoter) with HSV antibody staining,^{504,532} (b) two selected mutations appear to avoid second-site mutations with reversion to wild-type phenotype ($\gamma_134.5$ and ribonucleotide reductase deletions),¹²⁹⁴ (c) the retention of the native HSV TK allows for acyclovir susceptibility,¹⁷⁴ (d) the safety of these constructs was established in susceptible primates (*Aotus*),¹²⁹⁴ and (e) HSV could be used to successful vector genes.^{24,201,362,845}

Indeed, one construct, namely G207⁷¹⁸ demonstrated an adequate safety profile in both cell culture and animal models^{478,1112} and was efficacious in several tumor models *in vivo*.^{118,174,504,532,712,718,754} This candidate therapeutic is deleted in both copies of the $\gamma_134.5$ gene as well as ribonucleotide reductase. Sufficient quantities of virus were produced under

good manufacturing practice (GMP) conditions for a phase I study in humans with recurrent glioblastomas, as described later.

Numerous other constructs have been developed, including cytokine/chemokine genes, enzymes, and receptors.⁷¹⁰ However, other investigators have taken the approach of altering host recognition of HSV by deleting the $\alpha 47$ gene and thereby allowing host MHC-I processing. The status of these viruses is summarized in the next eight construct.

HF10

HF10 is a nonengineered virus, derived following serial passage of the wild-type HSV-1 strain HF.⁸¹³ This virus is not neuroinvasive and was determined to have stable duplications in the *UL53*, *UL54*, and *UL55* genes, as well as deletion of the *UL56* gene. Notably, HF10 contains both native copies of the $\gamma_1 34.5$ neurovirulence gene; however, its lack of neuroinvasiveness is presumably attributable to the absence of *UL56*, or to *syn* alterations that may also have an effect.¹¹⁷⁶ HF10 has been evaluated in murine models of peritoneal tumor distribution as well as breast and bladder cancer.^{576,1122,1137} Preliminary clinical studies of HF10 demonstrated its safety following intratumoral injection into metastatic squamous cell carcinoma of the head and neck, as well as metastatic breast cancer.^{355,549} A phase I clinical trial investigating the safety of HF10 in patients with refractory head and neck cancer is recruiting patients. This study will directly inject 1×10^5 to 1×10^7 pfu into squamous cell carcinoma of the head and neck that failed standard of care chemotherapy and radiation (Clinical Trial ID NCT01017185).

HSV1716

HSV1716 is one of two conditionally replication-competent, engineered HSVs directly injected into malignant glioma with demonstrated safety and the absence of neurovirulence. HSV1716 has been clinically studied for the treatment of malignant glioma in the United Kingdom. A series of phase I studies of direct intratumoral and surrounding normal parenchyma administration of HSV1716 at doses ranging from 1×10^3 to 1×10^5 pfu proved safety and, subsequently, viral replication in the tumor.^{426,840,913}

HSV1716 has also been assessed as a therapy for oral squamous cell carcinoma (1×10^5 pfu of virus intratumorally) and melanoma with evidence of safety but no documentation of viral replication.^{693,696}

NV1020

First engineered as a vaccine to prevent HSV-1 and HSV-2 infections, NV1020 is notable in that it is deleted in only one of the two $\gamma_1 34.5$ genes.⁷³⁹ NV1020 has been studied as an oncolytic HSV for hepatic colorectal adenocarcinoma metastases at doses ranging from 3×10^6 to 1×10^8 pfu followed by chemotherapy 2 to 3 days later.⁵³⁹ Serious adverse events were minimal. Concomitant sampling of the hepatic vein for viral DNA by PCR detected little evidence of systemic exposure, a perceived risk of administering virus intra-arterially. Additional phase I studies have been performed that support the safety of this approach, including multiple infusions at doses of 1×10^8 pfu.^{357,364} Efficacy cannot be determined from these studies; however, the investigators concluded that NV1020 may render infected malignant cells moderately susceptible to chemotherapy regimens against which they are resistant.

G207

G207, derived from the HSV-1 (F) strain, is deleted for both $\gamma_1 34.5$ genes and is further attenuated by insertion of the *lacZ* gene into the *UL39* locus, preventing expression of ribonucleotide reductase. G207 was demonstrated to be safe following direct intracranial injection in both mice and in highly susceptible *Aotus nancymae* primates.^{478,1112}

The first phase I safety trial with G207 evaluated direct intratumoral injection of virus in escalating doses ranging from 1×10^6 to 3×10^9 pfu. A total of 21 patients with recurrent grade III to IV malignant glioma were enrolled in the trial.⁷¹³ Even at the highest dose (3×10^9 pfu), no significant adverse events related to G207 administration were reported. Importantly, no evidence of encephalitis was apparent in any biopsy samples taken to monitor tumor progression or at postmortem.

Additional phase Ib studies in patients with recurrent glioblastoma multiforme have utilized various designs to define safety upon injection into a resected tumor bed, the ability of the virus to replicate in tumors, the effect of multiple administrations, and the definition of the contribution of radiation to improved outcome.⁷¹¹ At total doses of 1.15×10^9 pfu of G207, the results continue to define safety, evidence of virus replication at the highest doses, radiographic improvement, and some long-term survivors. Further studies are in progress.

G47 Δ

G47 Δ , directly derived from G207 and thus lacking both $\gamma_1 34.5$ gene copies as well as containing a *lacZ* gene insertion within *UL39*, is additionally deleted for the $\alpha 47$ gene. This latter modification prevents G47 Δ from down-modulating MHC-I presentation and additionally alters the kinetics of *UL11* gene expression from late to early in infection.¹¹⁵⁰ These modifications increase the immunogenicity and replicative ability of G47 Δ without affecting neurovirulence.¹¹⁵⁰ G47 Δ reduces tumor mass in multiple models.¹¹⁴⁹ The *in vivo* efficacy of G207 and G47 Δ have been directly compared, with G47 Δ providing an equal or improved survival advantage over G207.^{659,1150,1186} A phase I/II clinical trial investigating the safety and efficacy of G47 Δ in recurrent glioblastoma multiforme is recruiting patients in Japan.

OncoVEX^{GM-CSF}

OncoVEX^{GM-CSF} is derived from the pathogenic clinical isolate JS-1.⁶⁵⁴ Attenuations in this vector include replacement of both $\gamma_1 34.5$ genes with the gene encoding human granulocyte-macrophage stimulating factor (GM-CSF) and deletion of the $\alpha 47$ coding sequence such that the *UL11* gene is expressed from the immediate-early $\alpha 47$ promoter. OncoVEX^{GM-CSF} is “armed,” meaning that it expresses a transgene hypothesized to enhance antitumor effects by complementing the lytic mechanism of tumor clearance. In the case of OncoVEX^{GM-CSF}, this additional mechanism is immune stimulation through the cytokine GM-CSF—a hematopoietic growth factor that promotes the maturation and development of DCs as well as elicits the formation of Th1 skewed immune responses. OncoVEX^{GM-CSF} is the first armed oncolytic HSV vector to be evaluated in clinical trials.

OncoVEX^{GM-CSF} has been evaluated in several phase I clinical trials enrolling patients with refractory cutaneous or subcutaneous metastases of breast, gastrointestinal adenocarcinoma, malignant melanoma, or epithelial cancer of the head

and neck.⁴⁷¹ Direct intratumoral injection of one or three doses (1×10^6 – 1×10^8 pfu) established safety. OncoVEX^{GM-CSF} is being evaluated in malignant melanoma.¹⁰²⁹ No severe events have been attributable to virus administration. In addition, 13 patients have achieved no evidence of disease (NED) status, 10 of which achieved this status through the effects of the vector alone, with no additional therapy. A randomized, controlled phase III trial has been under way since April 2009 to investigate OncoVEX^{GM-CSF} for the treatment of patients with nonresectable stage III and IV malignant melanoma.

The safety of OncoVEX^{GM-CSF} has also been demonstrated in stage III and IV head and neck squamous cell carcinoma (HNSCC) in a phase I/II trial. A randomized controlled phase III study is planned to establish efficacy.

rRp450

rRp450 is derived from the first-generation vector hrR3. hrR3 was engineered by replacing the *U_L39* gene encoding RR of the wild-type strain KOS with *lacZ*. rRp450 followed with the replacement of the *lacZ* genes with the *CYP2B1*, the gene encoding the rat cytochrome p450 enzyme responsible for prodrug metabolism.¹⁸⁰ Cytochrome p450 2B1 expression is hypothesized to serve as a method of concentrating active metabolites of chemotherapeutics in malignant cells. It is notable that rRp450 retains both native copies of $\gamma_{134.5}$. Preclinical studies with rRp450 demonstrated its selective replication in tumor cells with increased expression of mammalian ribonucleotide reductase, demonstrating a level of targeting afforded by the ICP6 deletion, as well as increased cytotoxicity of these cells when infection was combined with nitrogen mustard alkylating agents *in vitro*.¹⁸⁰ *In vivo* studies demonstrated synergistic efficacy of rRp450 and cyclophosphamide against a model of hepatic metastases of colon adenocarcinoma in mice.⁸⁵⁴

M032 and C134

The engineered HSV recombinants M032 and C134 are similar in that both were originally derived from the wild-type HSV-1 (F) strain. They share identical deletions of the $\gamma_{134.5}$ gene but differ with regard to the inserted genes replacing $\gamma_{134.5}$. M032 expresses the human immunostimulatory cytokine IL-12, which promotes the activation of IFN- γ secretion and Th1 polarization of CD8⁺ T lymphocytes and also has antiangiogenic effects. Preliminary studies of a murine IL-12 expressing virus M002 demonstrate increased survival in intracranial tumor-bearing mice treated with M002 and increased infiltration of innate and adaptive immune cells into tumors.⁸⁴⁵ An Investigational New Drug (IND) application has been submitted to evaluate the safety of M032 in patients with recurrent glioblastoma and is awaiting FDA approval. C134 expresses the CMV PKR evasion and IFN- γ resistance molecule IRS1.¹⁰³⁰ IRS1 has equivalent functions as the $\gamma_{134.5}$ gene product ICP34.5 in terms of PKR evasion; however, unlike ICP34.5, it does not contribute to neurovirulence. Cells infected with C134 do not undergo PKR-mediated host protein shutoff. This has been found to occur in neuroblastoma cell lines, prompting the submission of an IND application for a phase I clinical trial of C134 in pediatric patients with neuroblastoma.¹⁶⁶

Summary

Engineered HSV constructs have been proven consistently safe when administered intracranially to humans at high doses. With

some constructs, suggestions of efficacy are apparent. Likely, no one construct or approach will cure all tumors. Future work will need to improve replication competence without sacrificing safety, improved delivery, and a better understanding of host gene expression to optimize the oncolytic approach.

ANTIVIRAL THERAPY

Advances in the treatment of HSV infections have led the way in the development of antiviral therapeutics. In the 1970s, vidarabine (adenine arabinoside) became the first licensed antiviral therapeutic for the treatment for herpes simplex encephalitis and neonatal HSV infections, as well as varicella zoster virus infection. Quickly, however, vidarabine was replaced by acyclovir in the physicians' armamentarium for the treatment of all HSV infections. Today, acyclovir and its prodrug valacyclovir, as well as the prodrug of penciclovir, famciclovir, are the most useful and widely used therapeutics for the treatment of HSV infections. Both valacyclovir and famciclovir have a distinct advantage over acyclovir. Specifically, the oral bioavailability of acyclovir following valacyclovir administration allows for improved pharmacokinetics. The same case is also made of plasma levels of penciclovir following famciclovir administration. The mechanism of action of acyclovir and penciclovir are summarized in Chapter 13. Brief reference will be made to the use of these medications, as well foscarnet and cidofovir, in the management of HSV infections.

Table 60.4 summarizes the use of the antiviral therapeutics in the treatment of HSV infections. A brief summary of the status of therapy for these entities is provided.

Life-threatening HSV infections, including herpes simplex encephalitis, neonatal HSV infection, and progressive or visceral disease in the immunocompromised host, are routinely treated with intravenous acyclovir. For infections involving the CNS, most notably herpes simplex encephalitis, mortality is decreased from 70% in placebo recipients to 25% in those who receive intravenous acyclovir therapy. Of the survivors, only one out of three returns to normal function. For neonatal HSV infection, multiorgan disseminated involvement, as defined earlier, can be treated with acyclovir with a resultant mortality of 25%. Neonatal HSV encephalitis is associated with a mortality of 5% following therapy. For both of these entities, survivors are left with significant neurologic impairment in most cases, namely 60%. Factors that predict a poor outcome include disseminated intravascular coagulopathy and prematurity for those babies with disseminated neonatal herpes, whereas for those with encephalitis seizures and prematurity predict a poor neurologic outcome.^{551,1241,1243,1249} These data indicate the requirement for improved therapies of HSV infections of the CNS.

Recently, 6 months of suppressive acyclovir therapy, following 3 weeks of intravenous therapy, has been shown to improve neurologic outcome for newborns with brain disease.⁵⁵³ In a placebo-controlled clinical trial, the treated babies had Bayley Developmental scores that were 30 points higher on average than the controls. These data suggest that low-grade continuing viral replication in the brain can be suppressed.

The concomitant use of monoclonal antibodies, as has been demonstrated in animal models, may prove effective adjunctive therapy. Similarly, the evaluation of anti-inflammatory

TABLE 60.4 Drugs for Herpes Simplex Virus

Infection	Drugs	Adult dosage ^a
Orolabial	<i>Topical</i>	
	Acyclovir:	5% cream 5×/d × 4 d
	Ointment	
	Docosanol	10% cream 5×/d until healing
	Penciclovir	1% cream applied q2h while awake × 4
	<i>Oral</i>	
Genital	Acyclovir	400 mg PO 5×/d while awake × 4
	Famciclovir	400 mg PO bid × 7 d
	Valacyclovir	2 g PO q12h × 1 d
	First episode	
	Acyclovir	400 mg PO tid or 200 mg PO 5×/d × 7–10 d ^b
	Famciclovir	250 mg PO tid × 7–10 d
	Valacyclovir	1 g PO bid × 7–10 d
	Episodic treatment of recurrences	
	Acyclovir	800 mg tid or 400 mg PO tid × 3–5 d
	Famciclovir	125 mg PO bid × 5 d
Suppression of recurrences	Valacyclovir	500 mg PO bid × 3 d
	Acyclovir	400 mg PO bid
	Famciclovir	250 mg PO bid
Mucocutaneous (immunocompromised)	Valacyclovir	500 mg or 1 g PO 1×/d
	Acyclovir	5 mg/kg IV q8h × 7–14 d or 400 mg PO 5×/d × 7–10 d
	Famciclovir	500 mg bid × 7–10 d
Encephalitis	Valacyclovir	500 mg or 1 g bid × 7–10 d
	Acyclovir	10–15 mg/kg IV q8h × 14–21 d
Neonatal	Acyclovir	20 mg/kg IV q8h × 14–21 d
Keratoconjunctivitis	Trifluridine	1% solution 1 drop q2h (max 9 drops/d)
Acyclovir resistant (severe infection, immunocompromised)	Foscarnet	40 mg/kg IV q8h × 14–21 d

^aDosage adjustment may be required for renal insufficiency.

^bFor severe initial genital herpes, IV acyclovir (5–10 mg/kg q8h for 5–7 d) can be used.

Note: Generic and trade names of drugs are as follows: acyclovir (Zovirax), docosanol (Abreva), penciclovir topical (Denavir), famciclovir (Famvir), valacyclovir (Valtrex), trifluridine (Viroptic), and foscarnet (Foscavir).

drugs, namely corticosteroids, early in the course of neurologic disease, might be beneficial. A lipophilic derivative of cidofovir, CMX001, may help to improve outcome, because it penetrates the CNS to a greater extent than acyclovir and does not have nephrotoxicity. Regardless, alternative therapeutic strategies for both herpes simplex encephalitis and neonatal HSV infections need to be developed.

Ocular HSV infections are routinely treated with topical trifluorothymidine with or without concomitant oral acyclovir, valacyclovir, or famciclovir therapy. Topical vidarabine and idoxuridine have also been used for ocular infections. Acyclovir, and likely valacyclovir and famciclovir, can be used to suppress recurrences of HSV keratoconjunctivitis. However, it should be noted that no clinical trials of valacyclovir or famciclovir have been performed for this entity.

The most significant advances in antiviral therapy have been achieved in the management of mucocutaneous HSV infections. The prototypic treatment and suppressive regimens have been developed for the management of genital HSV infec-

tions. Acyclovir, valacyclovir, and famciclovir are efficacious in the treatment of both primary and recurrent genital HSV infections. Valacyclovir and famciclovir⁹⁷⁹ can be administered to patients on a suppressive basis to prevent reactivation of infection.⁵⁵² Although these medications significantly reduce the frequency of recurrences, and therefore the probability of reactivation, periodic excretion of virus still occurs during suppressive therapy and can result in person-to-person transmission of infection. Indeed, even valacyclovir at approved doses does not prevent intermittent shedding of HSV.²³⁴ In a seminal clinical trial, valacyclovir has been shown to decrease person-to-person transmission by approximately 48% when drug is administered once daily at 500 mg.²³⁴ Suppressive therapy can be successfully achieved with valacyclovir administered once daily, whereas famciclovir requires twice-daily dosing for suppression. Both valacyclovir and famciclovir^{28,979} can be administered for short periods of therapy (3 days and 1 day, respectively) to treat recurrences of genital herpes with efficacy compared to standard treatment regimens.^{517,554}

Acyclovir, valacyclovir, and famciclovir are approved for the treatment of herpes labialis. As with genital HSV infection, short-course therapy provides excellent therapeutic results. At the present time, although acyclovir has been studied for the management of HSV gingivostomatitis, registrational trials have not been submitted to the FDA.

HSV infections in the immunocompromised host pose unique challenges. Intravenous acyclovir is used routinely for progressive and/or life-threatening disease. Valacyclovir and famciclovir are useful in the management of HSV infections in individuals with HIV/AIDS. However, in some patient populations, progressive disease occurs in the presence of intravenous acyclovir therapy, implying the development of resistance. The propensity to develop resistance to these medications is greatest in hematopoietic stem cell transplant recipients and in individuals who have advanced HIV/AIDS with low CD4 counts. When HSV isolates are mapped for resistance, the most common mutations are found in TK. Alternatively, mutations have been detected in HSV DNA polymerase, rendering acyclovir triphosphate and penciclovir triphosphate ineffective. Under such circumstances, foscarnet or, rarely, cidofovir, drugs with alternative mechanisms of action have been employed.

Future Needs

The development of new antiviral agents for the management of HSV infection has been stymied by the overwhelming success of drugs such as acyclovir, valacyclovir, and famciclovir. In large part, the pharmaceutical industry does not identify a niche for the development of future antiviral drugs in this area. Regardless, the persistent mortality and elevated morbidity in patients with HSV infections of the CNS defines a medical need for which improved therapy should be developed. Recently, a new helicase/primase inhibitor has been shown to be safe and effective for the treatment of genital HSV infection.¹¹⁶⁷

B VIRUS

B virus, endemic in macaque monkeys, has the unique distinction of being the only one of nearly 35 identified nonhuman primate herpesviruses that is highly pathogenic for humans.¹²³⁷ The unique biology of B virus includes its neurotropism and neurovirulence. Because untreated B virus infections are associated with high mortality in humans, individuals handling macaques or macaque cells and tissues are at risk for infection. Human infection is associated with a breach of skin or mucosa and subsequent infection with virus. Fomites and contaminated particulates or surfaces can serve as a source of virus infection. Human-to-human transmission has been documented. Prior to the advent of antiviral therapy, the mortality was 80%. However, since the early 1980s, 80% of infected individuals have survived.

History

In 1932, a young physician (WB) was bitten by a monkey and later developed localized erythema at the site of the animal bite that was followed by lymphangitis, lymphadenitis, and, ultimately, a transverse myelitis with demise ascribed to respiratory failure. Autopsy tissue specimens revealed an ultrafilterable agent recovered from neurologic tissues that caused a cytopathic effect in tissue culture similar to HSV.³⁶³

Within a year of this first report, Sabin independently also found an ultrafilterable agent in the tissue of this index patient. He identified this as “B” virus,⁹⁷⁸ naming the virus by the initial of the patient’s last name. Thus, the virus subsequently has been called *herpes B virus*, *herpesvirus simiae*, *Cercopithecine herpesvirus 1*, or more simply, *B virus*. The virus was also noted to share similarity with pseudorabies, among other viruses, including SA8 and two additional nonhuman primate alphaherpesviruses: HPV-2 and Langur herpesvirus.^{139,140,307,926} Because of neurovirulence in a foreign host, B virus is considered by some to be one of the most dangerous occupational hazards for those who work directly with macaques or their tissues or with monkeys who have been in contact with macaques.

Disease Pathogenesis and Clinical Presentation

The most striking characteristic of human B virus infection is the involvement of the CNS, specifically the upper spinal cord and brain stem. These areas are the principal sites for virus replication. For the most part, human disease reflects the sites of viral replication; however, there is great variability in presentation. Most often, illness is apparent within days to weeks; however, in some cases, there appears to be a delay in development of acute disease. The reasons for this delay are unknown, and although rare, delays may even range from months to years, making diagnosis difficult. Once symptoms appear, the clinical progression is associated with relatively consistent symptoms, including influenza-like illness, lymphadenitis, fever, headache, vomiting, myalgia, cramping, meningeal irritation, stiff neck, limb paresthesias, and urinary retention with an ascending paralysis culminating in respiratory failure, requiring ventilatory support. Cranial nerve signs, such as nystagmus and diplopia, are common in most published cases. Sinusitis and conjunctivitis have been observed in some cases.¹²³⁷ The array of symptoms may be related to the dose of virus with which the individual was infected or the route of inoculation. Ophthalmic zoster-like symptoms have been reported as well,³³³ and in one particular case, reactivation of latent infection was postulated. A summary of descriptions of human cases can be found in a comprehensive review.¹²³⁷

Virus can be recovered at skin sites of inoculation for extended periods of time, and viral DNA can be detected in cerebrospinal fluid by the time neurologic symptoms are experienced. Virus has also been recovered from throat, buccal, and conjunctival sites as well as from lesions, vesicles, or injury sites as late as weeks to months after infection. Most clinical cases are associated with bites (50%), fomites, (8%) saliva (<5%), and aerosols (10%). Histopathologic findings included edema and degeneration of motor neurons. Even with advanced disease, Cowdry type A eosinophilic intranuclear inclusions are uncommon. Gliosis and astrogliosis are late histopathologic findings; thus, there can be evidence of myelitis, encephalomyelitis, or encephalitis, or combinations of each of these conditions. Histopathologic examination of the eye has revealed a multifocal necrotizing retinitis associated with a vitritis, optic neuritis, and prominent panuveitis. B virus can infect and destroy retinal tissue similar to that of other herpesviruses.

The highest percentage of deaths occurs within a few weeks after onset of disease. In some cases, however, life was prolonged artificially for months or years. Surviving cases have varying degrees of morbidity, ranging from little or no neurologic impairment to more extensive CNS involvement.^{31,122,128}

Some survivors experience slow neurologic decline, whereas others report few, if any, long-term effects. In several reports, ocular disease has been reported.³³³

Control of B Virus Infection

Multiple levels of prevention are used to prevent B virus infection in both humans and nonhuman primates, ranging from attempts to eliminate virus from colonies to designing methods to work safely in environments where there is increased risk for contracting this agent. The Centers for Disease Control and Prevention (CDC) has published detailed guidelines for maximizing protection of individuals working with macaque monkeys.^{169,170,216,458} Further, the National Institutes of Health's (NIH) National Center for Research Resources has funded the development of B virus-free colonies for NIH-funded research involving these animals in an attempt to eliminate this virus from colonies used for biomedical research. Nonetheless, B virus-infected monkeys are plentiful and can be handled safely if strict guidelines are followed, including barrier precautions.

When B virus is detected, inactivation is accomplished with either heat or formaldehyde.¹²³⁷ Other virus inactivators include detergents and bleach; however, individuals who are working in a decontaminated area should still be alert for injury prevention. Minimizing fomites decreases worker risk and reduces virus spread among animals. One B virus infection in a human was acquired from a cage after sustaining a scratch, underscoring that surface decontamination can play an important role in infection control.

No vaccine is available; thus, only antiviral therapy is recognized as effective in prevention when administered early after exposure.^{114,217,458,1224} For B virus disease, acyclovir and the related family of nucleoside analogs were noted to be effective when given in high doses—for example, acyclovir at 10 mg/kg intravenously three times daily for 14 to 21 days.⁴⁵⁸ Some physicians follow intravenous therapy with long-term oral suppression (acyclovir, valaciclovir, or famciclovir). Ganciclovir, which has a greater efficacy *in vitro* and thus was used in a few cases since 1989 with success, has been recommended by some experts as the treatment of choice for CNS disease associated with B virus. Antivirals are used by an increasing number of facilities for postinjury prophylaxis or after laboratory results indicate that an animal may have been actively infected around the time of the exposure. Postinjury prophylaxis has been performed with acyclovir, famciclovir, or valaciclovir, and these have demonstrated efficacy *in vitro*. Recommendations and guidelines have been published by the CDC and can be readily accessed.²¹⁶ Only a handful of physicians have had experience in the treatment of B virus zoonosis, and their participation and expertise has been important in the development of the CDC guidelines.

Finally, with respect to prevention, the value of immediate wound cleansing and first aid after a potential exposure owing to a bite, scratch, splash, or other suspicious injury is very important. Guidelines for wound cleaning are described in detail by the CDC (<http://www.cdc.gov/herpesvirus/firstaid-treatment.html>). Every institution working with macaques should have an injury protocol with immediate availability of first aid, a secondary care plan, and an infectious disease specialist who is a member of the institution's prevention and care response team.

HISTORY

While descriptions of patients with symptoms resembling infectious mononucleosis were reported in the medical literature in the late 19th century, infectious mononucleosis was first named in 1920.¹³⁸⁷ The initial description of the use of heterophile antibodies to diagnose infectious mononucleosis was in 1932.¹¹⁴³ In 1958, Denis Burkitt¹⁴⁴ described a tumor involving the jaws in Africans in areas where malaria was holoendemic, and this tumor is now referred to as Burkitt lymphoma. Epstein-Barr virus (EBV) was discovered using electron microscopy to detect viral particles in cultured Burkitt lymphoma cells in 1964 by Epstein et al.³⁶³ Gertrude and Werner Henle⁵⁶⁰ described an immunofluorescent antibody test for the virus in 1966 and found that patients with Burkitt lymphoma as well as most Americans had antibody to EBV. In 1968, EBV was shown to be a cause of infectious mononucleosis.⁵⁶² Three years later, in 1971, EBV was found to transform human B lymphocytes in cell culture,¹⁰⁹⁴ and in 1984, the virus was shown to replicate in human epithelial cells.¹³⁵⁴ Strong epidemiologic evidence that EBV was a cause for Burkitt lymphoma came from pioneering studies of de-The and colleagues.³⁰³ Since its initial discovery in Burkitt lymphoma, the virus was found in nasopharyngeal carcinoma in 1970,¹⁶⁴⁵ in non-Hodgkin lymphoma in patients with acquired immunodeficiency syndrome (AIDS) in 1982,¹⁶³⁵ in T-cell lymphoma in 1988,⁶⁹⁸ and in Hodgkin lymphoma in 1989.¹⁵³⁸ The virus has been associated with other malignancies. Its relationship to other diseases such as multiple sclerosis and systemic lupus erythematosus is uncertain.

CLASSIFICATION

The gammaherpesvirus subfamily consists of the gamma 1 or *Lymphocryptovirus* (LCV) genus, which includes EBV and other primate lymphocryptoviruses, and the gamma 2 or *Rhadinovirus* (RDV) genus, which includes herpesvirus saimiri (HVS) and Kaposi's sarcoma-associated herpes virus (KSHV) as well as related viruses of primate and non-primate species.^{15,1256} Many Old

FIGURE 61.1. Schematic depiction of the linear Epstein-Barr virus (EBV) genome. A: Linear representation of the overall genome arrangement with the unique short (US) and unique long (UL) regions shown. Within the genome the terminal repeats (TR), internal repeats (IR1 to 4), and unique sequence domains (U1 to U5) of the EBV genome are depicted in proportion to their overall size. The position of the *cis*-acting element for episome maintenance and replication in latent infection, oriP, is indicated. The origins for EBV DNA replication in lytic infection (oriLyt) are in U3 and U5 just to the right of IR2 and IR4, respectively. The deletions in B95-8 and P3HR-1 genomes are shown.^{540,681,700}

World and some New World primate species have endemic LCVs that are collinearly homologous to EBV.^{114,229,230,375,376,451,452,551–553,1226,1227} In contrast, RDVs are endemic not only in most primate species but also in many subprimate mammalian species.^{14,16,288,361,1005,1433} Overall, the nucleotide sequences of gammaherpesvirus genomes have substantial collinear homology and much less co-linearity and homology with alpha- and betaherpesvirus genomes.^{288,1005}

Amongst the gammaherpesvirus genomes, LCVs are likely to have evolved from RDVs. RDVs have more diverse genomes than LCVs, are endemic in more diverse mammalian species, and characteristically have multiple cell complementary DNAs (cDNAs) in their genomes.^{288,1005} Old World LCVs have collinear homologous genomes with a unique group of recently evolved nuclear protein genes, which lack homology to RDV or cell genes and are only partially present in New World LCV genomes.¹²²⁶ New World LCVs may be intermediates in the evolution of Old World primate LCVs.

Aside from the absence of two nuclear protein 3 genes in the marmoset LCV genome, LCV genomes are very similar to each other in structure, gene organization, and collinear homology. The LCV genome shared features include 0.5–kilobase pair (kbp) tandem terminal direct repeats (TR), 3-kbp tandem internal direct repeats (IR1), and short tandem internal direct repeats (IR2, IR4)^{280,281,468,1198} (Fig. 61.1). RDVs have longer and more highly reiterated TRs and lack long internal direct repeats. Old World primate LCV genes encode latency 3–associated nuclear antigen proteins EBNA-2, EBNA-3A, EBNA-3B, EBNA-3C, and EBNA-1, which are expressed when EBV growth transforms primary B lymphocytes to lymphoblastoid cell lines (LCLs). LCVs also include genes that encode integral membrane proteins important for efficient latency 3 infection—associated B-lymphocyte growth transformation and survival,^{388,730,921} genes that encode two small nonpolyadenylated EBV-encoded small RNAs (EBERs),^{615,859} genes that encode differentially spliced Bam A rightward transcripts, genes that encode an interleukin-10 (IL-10) and a bcl-2 homolog,^{1043,1144} genes that encode distinctive microRNAs (miRNAs),^{151,1162,1163} and a gene that encodes a glycoprotein that binds to the B-lymphocyte surface protein, CD21.^{1080,1427,1428}

The EBV genome and gene organization is shown in Figures 61.1 and 61.2.¹²⁷⁹ EBV was the first herpesvirus genome to be completely cloned in sets of overlapping fragments,^{280,1198} based in part on previously derived restriction endonuclease

maps.⁴⁶⁶ The EBV genome was subsequently sequenced from BamHI-digested cloned DNA fragments⁶⁵ and open reading frames (ORFs) were designated by their order in a rightward or leftward direction within each BamHI fragment (Fig. 61.2). The majority of KSHV-predicted ORFs are collinearly homologous to ORFs of EBV.¹²⁵⁶ The mean amino acid identity to EBV among the 54 homologous KSHV ORFs is 35%, with only two ORFs less than 21%.

Herpesvirus DNAs have conserved distantly homologous gene blocks with conserved gene order and collinear homology at the predicted protein level.^{288,1005} Gammaherpesvirus genes conserved with alpha- and betaherpesviruses are primarily genes that encode proteins involved in nucleotide metabolism, proteins that replicate and process viral DNA, and proteins that make up the structural components of the virion capsid, tegument, and envelope. Genes that are at least partially shared among the gammaherpesviruses and have more limited representation in the genomes of other herpesviruses include BZLF1 and BRLF1, which encode the immediate early regulators of viral gene expression; BALF1, which encodes a bcl-2 homolog; and LMP1 and LMP2, which encode integral membrane proteins with 6 and 12 membrane-spanning domains, respectively. LCVs and RDVs also have analogous but nonhomologous DNA sequences and nuclear proteins that are necessary and sufficient for persistence of the genomes as episomes in dividing cells.^{72,266,1588}

The gammaherpesvirus subfamily classification was initially established on the basis of biologic properties including oncogenic associations, restricted host range for infection in cell culture, and episome persistence in dividing cells. Gammaherpesviruses also establish latent infection in lymphocytes but are not unique in this regard. Betaherpesviruses such as human herpesvirus 6 (HHV-6), HHV-7, and even cytomegalovirus (CMV) can also latently infect lymphocytes and other hematopoietic cells. Segregation into the gammaherpesvirus subfamily based on nucleotide and protein sequence homology and genome collinearity provides a more enduring basis for phylogenetic classification.^{288,1005} Taxonomists have named EBV as HHV-4. Although most authors still use the name EBV, some indexing services have adopted HHV-4.

Two EBV types circulate in most populations. EBV types 1 and 2 (also named types A and B) differ largely in nuclear protein genes that encode leader protein (EBNA-LP), EBNA-2, EBNA-3A, EBNA-3B, and EBNA-3C, which are expressed in latency 3 growth transformation of B cells to lymphoblastoid

FIGURE 61.2. Schematic depiction of the linear Epstein-Barr virus (EBV) genome with encoded open reading frames (ORFs). EBV ORFs are named based on their location (first ORF, second ORF, etc.) and direction (rightward or leftward) within the Bam H1 fragment (A, B, C, and so on, in decreasing size).⁶⁵ The prototypic EBV type 1 genome DNA sequence (171,820 bp) found in the National Center for Biotechnology Information (NCBI) is actually a composite of two viral genomes (B95-8 and Raji) due to deletions within the viral genome during passage in tissue culture.^{65,1136,1187} Size and direction of the ORFs are indicated, as are the noncoding RNAs EBER1 and EBER2. The latency-associated ORFs or exons that make up these ORFs are colored purple. The early lytic ORFs are beige and late lytic ORFs are shaded with red. Yellow arrows depict ORFs of unknown gene class or are hypothetical. LMP2A and LMP2B are encoded across the circularized genome. The locations of microRNA (miRNAs) encoded by the genome are shown. Numbers refer to kilobase pairs. (From Sample JT, Marendy E, Hughes DJ, et al. The Epstein-Barr virus genome. In: Damania B, Pipas JM, eds. *DNA Tumor Viruses*. New York: Springer, 2009, with kind permission from Springer Science+Business Media B.V.)

FIGURE 61.3. Electron micrograph and schematic diagram of Epstein-Barr virus (EBV) virions. A: EBV particles purified from the supernatant of B95-8 marmoset cells. Bar represents 100 nm. (A from Miller G, Lipman M. Comparison of the yield of infectious virus from clones of human and simian lymphoblastoid lines transformed by Epstein-Barr virus. *J Exp Med* 1973;138[6]:1398–1412, © 1973, Rockefeller University Press.) B: Diagram of EBV virion. The major structural components of the virion are shown including the virion envelope, which is studded with glycoproteins important for binding and subsequent fusion of the virion envelope with cellular membranes; the tegument, which contains both virus-encoded proteins and cellular proteins; the capsid; and the viral genome.

protein (BOLF1), 15-kD myristylated protein (BBLF1), 32-kD myristylated protein-binding protein (BGLF2), 58-kD capsid-associated protein (BVRF1), 58-kD packaging protein (BGLF1), 27-kD palmitylated protein (BSRF1), and 47-kD serine-threonine protein kinase (BGLF4), which are common components of herpesvirus teguments.⁶⁹⁵ In addition, EBV has a 140-kD major tegument protein (BNRF1), 19-kD BLRF2, 72-kD BRRF2, 54-kD BDLF2, and 42-kD BKRF4, which are gammaherpesvirus specific.⁶⁹⁵ Cell proteins actin, HSP70, cofillin, β -tubulin, enolase, and Hsp90 are also significant components of the EBV tegument, potentially related to cytoplasmic re-envelopment. The major glycoprotein components of the envelope are gp350 (BLLF1), gH (BXLF2), gB (BALF4), gp42 (BZLF2), gM (BBRF3), gp78 (BILF2), gN (BLRF1), gp150 (BDLF3), and gL (BKRF2).⁶⁹⁵ EBNA-1, LMP1, LMP2, gp64 (BILF1), BMRF2, and herpes simplex virus (HSV) homologs UL7 (BBRF2), UL14 (BGLF3), UL31 (BFLF2), and UL34 (BFRF1) are not detected in EBV virions.

GENOME STRUCTURE

The EBV genome is a linear, double-stranded DNA composed of 60 mole percent guanine and cytosine.^{65,758,1185} The prototypic EBV type 1 genome DNA sequence (171,820 bp) found in the National Center for Biotechnology Information (NCBI) is actually a composite of two viral genomes B95-8 and Raji due to deletions within the viral genome during passage in tissue culture (Fig. 61.1).^{65,1136,1187} Deletion during extensive passage in culture is a common feature of EBV because three other commonly used viruses, Daudi, Raji, and P3HR-1, also contain deletions.^{540,681,700} Recently, type 2 strains have been sequenced. The prototypic type 2 strain deposited in NCBI is 172,760 bp and as described earlier is highly homologous to type 1 DNA.³¹⁸

The characteristic features of EBV and most other lymphocryptovirus genomes include (a) a single overall format and gene arrangement^{280,466–468,1198}; (b) 2 to 5 tandem, 0.5-kbp, direct repeats of the same sequence at both termini (TR)⁴⁶⁸; (c) 6 to 12 tandem reiterations of a 3-kbp, internal direct repeat (IR1)²¹⁹; (d) short and long largely unique sequence domains (US and UL) that have almost all of the genome coding capacity; (e) perfect and imperfect tandem DNA repeats, most of which are within ORFs; and (f) a duplicated region, IR2, near the left end of UL, which consists of multiple, highly conserved, G-C-rich, tandem 125-bp repeats and 2 kbp of adjacent unique DNA, all of which have extensive homology to a region, IR4, near the right end of UL. IR4 is composed of G-C-rich, tandem 102-bp repeats and 1 kbp of nearby unique DNA.²⁸⁴ The IR2 and IR4 repeats are within ORFs. Because the IR2 repeat is 125 kbp and not divisible by three, sequential iterations are translated in different reading frames, resulting in an unusual protein. IR2 and IR4 also include the origins for initiation of viral DNA replication.^{524,1260}

The reiteration frequency of the EBV tandem perfect repeats becomes variable during viral DNA replication, with the average number of repeats being identical to the parent genome and most of the progeny having similar numbers of repeats as the parental genome. When EBV infects a cell, the genome becomes an episome with a characteristic number of TRs, dependent on the number of TRs in the parental genome and the unique cleavage and joining events of the single infecting viral genome. If infection is nonpermissive for viral replication and permissive for latent infection and continued cell growth, each EBV episome in progeny-infected cells will usually have the same number of TRs as the parent cell. Homogeneity or heterogeneity in the number of TRs is therefore useful in determining whether a group of latently infected cells arose from a single common progenitor infected cell or from multiple

progenitors.¹¹⁹⁹ The number of 3-kbp IR1 repeats also varies among EBVs and among progeny of EBV replication but is more difficult to assess as a marker of heterogeneity because of the 18- to 30-kbp total size. Other, smaller, imperfect, or less highly reiterated repeats within ORFs are more stable during replication but differ sufficiently among different virus isolates that the size of the encoded proteins can be used to uniquely identify each isolate.^{554,563-568,1014,1633}

STEPS IN REPLICATION

Attachment and Entry

EBV uses different glycoprotein combinations to infect B cells and epithelial cells (Fig. 61.4), but similar to other human herpesviruses, the core fusion complex consists of gB and gH/gL. gB and gH/gL were originally designated gp110 and gp85/gp25, respectively, but because of homologous proteins found

FIGURE 61.4. Schematic representation of Epstein-Barr virus (EBV) entry into epithelial and B cells. EBV enters epithelial cells by fusion at the plasma membrane and B cells by fusion with an endocytic membrane after endocytosis. For B-cell entry, EBV virions first bind to CR2/CD21 via gp350/220 (1). Following this interaction, gp42 binds to human leukocyte antigen (HLA) class II (2), triggering fusion mediated by gH/gL and gB (3). For epithelial cell entry, EBV virions may first bind via an interaction of integrins with BMRF2 (1). Following this binding, gH/gL binds to integrins (2) and triggers fusion mediated by gB (3). Following fusion, the capsid is released into the cytoplasm and is transported to the nuclear membrane by microtubule-mediated transport. The EBV genome is released into the nucleus through a nuclear pore. Latency can result, in which the genome is tethered to host chromosomes via an interaction with Epstein-Barr virus nuclear antigen 1 (EBNA-1). Lytic replication resulting in the production of viral genomes may also result, induced by the BRLF1 and BZLF1 EBV gene products.

in all human herpesviruses, these proteins are now generally referred to as gB and gH/gL. EBV gB is the fusogen for viral entry. The gB structure is composed of trimers nearly identical to the structure of HSV gB.^{64,548} The solved gB structure likely represents a postfusion conformation because the structure is very similar to the low-pH or postfusion form of the G protein of vesicular stomatitis virus.¹²³³ The mechanism of entry into two major target cells of EBV follows.

B Lymphocytes

B lymphocytes and epithelial cells are the major sites for EBV infection in the human host. EBV binding to B cells is mediated by CD21, also known as complement receptor 2 (CR2). Reflecting the importance of CD21 for B-cell infection, CD21 is abundantly expressed on B cells and binds the virus-encoded glycoproteins gp350/220.^{390,416,1081,1082,1427} gp350/220 has homologs in primate gammaherpesviruses but not in other human herpesviruses.¹⁵²² gp350 and gp220 are encoded by the same messenger RNA (mRNA), but a single splice generates the gp220 reading frame.^{88,639} No known distinct function of either gp350 or gp220 has been determined because they both contain the domain that binds CD21.¹⁴²⁸

CD21 is the receptor for the C3d component of complement and is part of a large family of complement regulatory proteins. Family members have one or more extracellular structural motifs known as short consensus repeats (SCRs). As well as being expressed on B cells, CD21 is expressed on other cell types including tonsillar epithelial cells.⁶⁸⁸ The extracellular domain of CD21 contains multiple SCRs, but only SCR-1 and SCR-2 are required for EBV and C3d binding.^{175,929,981} Soluble CD21 binds to the EBV virion and can block B-cell infection.¹⁰⁸³ The structure of the key gp350 binding domain on CD21 was solved¹¹⁸⁶ and the region of gp350 required for binding to CD21 is contained within a portion of gp350 that is not glycosylated.¹⁴¹⁶ Compatible with this finding, deglycosylated gp350 binds to CD21, as does the fully glycosylated gp350.¹⁴¹⁶

Binding of EBV virions or gp350 coated beads to CD21 results in capping of CD21 followed by endocytosis,^{1079,1427} consistent with a role of gp350/220 initiation of CD21 intracellular signal transduction in EBV B-lymphocyte entry.^{124,277,1348,1402,1427} The binding of gp350/220 to CD21 parallels the interaction of HSV gC with cell surface proteoglycans in tethering virions to target cells. This initial step is not absolutely required for infection because EBV deleted for gp350/220 or HSV-1 deleted for gC have only modest defects in virus entry.^{571,678} After binding to B cells, EBV virions are endocytosed¹⁰²⁵ and fusion of the viral membrane is thought to occur via the interaction of gp42 with human leukocyte antigen (HLA) class II followed by fusion mediated by gH/gL and gB.

HLA-DR was found to bind gp42 in an expression library screen for proteins that bound a soluble form of gp42.¹³⁸⁶ Both structural and functional studies have shown that gp42 exhibits features of the C-type lectin family^{1065,1386} and has no known sequence homologs in other human herpesviruses but is found in the EBV-related primate viruses.¹⁵²² The gp42/HLA-DR interaction is essential for EBV infection of B cells and antibodies to gp42 and HLA-DR block infection.^{876,877,1024} In addition, virus deleted for gp42 does not infect B cells unless soluble gp42 is provided *in trans* or polyethylene glycol is added to promote fusion.^{1530,1531} Also indicative of the important role

of gp42 in B-cell infection, virosomes lacking gp42 bind B cells but are unable to fuse.⁵¹⁵ The binding site of gp42 on HLA class II has been extensively studied by mutagenesis^{511,513} and by protein crystallography.¹⁰⁶⁵ Because of the key role of HLA class II in antigen presentation, studies have suggested that gp42 may block HLA class II antigen presentation, preventing CD4 T-cell activation.^{1220,1219,1386}

gp42 stably interacts with gH/gL and links receptor binding with fusion mediated by gH/gL and gB. The structure of gp42 unbound to a receptor indicates that a conformational change occurs upon binding of gp42 to HLA class II, widening a hydrophobic pocket on the surface of gp42, which suggests a conformational change is important in triggering fusion by engaging other components of the EBV fusion complex or a cellular ligand.⁷⁸⁰ The EBV gH/gL structure has also been solved,⁹⁹⁵ revealing an elongated rod-like shape with the middle being the widest and gL forming intimate contacts with the N-terminal residues of gH, compatible with the known chaperone function of gL for gH expression, processing, and transport.^{547,877,1039,1111,1586} Of particular interest, a KGD sequence on the gH/gL surface has been implicated in integrin binding and epithelial cell entry²¹⁷ and is near a potential gp42 binding domain.⁹⁹⁵ Competitive binding between gp42 and integrin to gH/gL is consistent with the observation that gp42 and gp42-derived peptides block fusion and entry of epithelial cells.^{121,778,779,908} Gp42 interacts with gH/gL via a domain contained within the amino terminus of gp42 located outside the gp42 C-type lectin domain.^{778,877,908}

EBV virions produced by B lymphocytes are deficient in gp42 as a consequence of gp42 binding to HLA class II instead of gH/gL during EBV lytic replication.¹²¹ EBV deficient in gp42 is defective in B-cell infectivity but is enhanced in epithelial cell infectivity.¹²¹ The absence of gp42 enables the gH/gL complex to engage an epithelial cell receptor,¹²² which is otherwise occluded by gp42. During virus egress from epithelial cells, the absence of HLA class II results in virions containing gp42 bound to gH/gL that efficiently infect B lymphocytes.

Epithelial Cells

In contrast to B-cell entry, EBV entry into epithelial cells occurs at the cell surface in the absence of endocytosis.¹⁰²⁵ In addition to CD21, which is expressed on tonsillar epithelial cells, suggesting the gp350/220 interaction with CD21 may be important for epithelial cell infection,⁶⁸⁸ BMRF2 may also have a role in epithelial entry. BMRF2 is a multispan membrane protein that contains an extracellular RGD motif that is a ligand for $\alpha 1$, $\alpha 5$, $\alpha 3$, and αv integrins.¹⁵⁶⁸ This interaction is important for infection of polarized epithelial cells,¹⁴⁷⁷ and antibodies to BMRF2 or $\alpha 5 \beta 1$ integrin block EBV infection of polarized epithelial cells through the basolateral cell surface. Interestingly, BMRF2 is not abundant in the EBV virion⁶⁹⁵ and appears not to have a role in fusion,⁵¹² so BMRF2 may function similar to gp350/220 to tether virions to target cells and induce signal transduction pathways. Integrin signaling has been shown to be important in HHV8 infection.¹³²⁹ Most recently, $\alpha v \beta 6$ and $\alpha v \beta 8$ integrins have been identified as epithelial cell receptors for gH,²¹⁷ and this binding triggers fusion in a two-step reaction.²¹⁶ Earlier studies had shown that a soluble form of gH/gL bound specifically to epithelial cells but not B cells.¹²² In

Genes in “EBV” column in italics are expressed in latent infection.

In the HSV and KSV columns, the homology with the genes in italics with EBV is not significant, but they may be positional homologs.

EBV, Epstein-Barr virus; HSV, herpes simplex virus; KSHV, Kaposi’s sarcoma–associated herpes virus; IL, interleukin; HLA, human leukocyte antigen; CSF-1, colony-stimulating factor-1.

addition, gH-null virus does not bind to epithelial cells,^{1039,1112} and a monoclonal antibody to gH/gL can reduce both gH/gL and virus binding.^{122,1039} These observations all point to an essential role of gH/gL in the infection of epithelial cells.

Other modes of EBV infection may also exist besides virus-induced membrane fusion. Virus coated with immunoglobulin A can bind to the polymeric IgA receptor.¹³⁵⁶ This form of infection may be relevant in nasopharyngeal carcinoma, where high levels of EBV-specific IgA antibodies are found in the blood.⁵⁶¹ However, EBV is transcytosed in polarized epithelial cells without evidence of replication.⁴⁴⁴ Interestingly, antibodies directed against gp350/220 can enhance EBV epithelial infection independent of Fc receptor interactions, and cell contact also enhances epithelial infection.^{653,1328,1479} Finally, cell-associated virus is very efficient in infecting epithelial cells or B cells.^{653,1326,1327,1328}

Transcription: Transformation of Primary B Lymphocytes by EBV

One of the most interesting aspects of infection by EBV is the ability of the virus to immortalize B lymphocytes in cell culture and establish a largely latent infection in which few viral genes are expressed. B lymphocytes infected with EBV become immortalized and proliferate indefinitely as lymphoblastoid cell lines (LCLs). It is this characteristic of EBV that likely contributes to the association of EBV with human cancers. This section will focus on viral genes expressed in LCLs because these genes have been extensively studied. Only a subset of the approximately 80 genes encoded by EBV are abundantly expressed in latently infected B lymphocytes (Table 61.1). In addition to protein products, a number of RNAs are expressed, including the EBERs and microRNAs. The major proteins expressed are either nuclear (EBNAs—Epstein-Barr

nuclear antigens) or found in cellular membranes (LMPs—latent membrane proteins). Their known or proposed functions are shown in Table 61.1. These genes are not conserved in any other human herpesvirus, but homologs to these genes have been identified in the related LCVs that infect non-human primates.

In addition to the pattern of viral gene expression observed in LCLs, EBV establishes other patterns of gene expression in EBV-positive tumors and in the blood of infected persons. In latency 1, defined by Burkitt lymphoma, only EBNA-1 protein is expressed, although recent studies have shown other latency-associated proteins are sometimes expressed (described later). In latency 2, characterized by nasopharyngeal carcinoma, EBV-positive Hodgkin lymphoma, and T-cell lymphoma, EBNA-1, LMP1, and LMP2 are expressed. In latency 3, defined by LCLs grown *in vitro*, all the known latent genes are expressed. More recent studies analyzing expression of viral genes in immunocompetent individuals latently infected with EBV have shown that few if any EBV genes are expressed in virus-infected B lymphocytes in the blood, resulting in EBV latency 0.

Following infection of primary B cells, host cell RNA polymerase II transcribes viral mRNAs with the first transcripts resulting from Wp promoter encoding EBNA-LP and EBNA-2 (Fig. 61.5).^{17,1189,1274,1303,1381,1382,1491,1521,1548,1600,1601} The Wp upstream regulatory element extends from -1168 to -87

and has components that bind YY1, RFX1, RFX3, MIBP1, CREB /ATF-1, and BSAP/Pax5 that provide B-cell specificity.^{90,776,1223,1449} Early in infection of primary B cells, Wp is used exclusively to drive transcription of the EBNA genes, followed by an EBNA-2 and EBNA-1 induced switch to use of the Cp promoter.^{1550,1552,1566} Interestingly, recent data suggest a novel posttranscriptional mechanism for *trans*-repression of Wp-dependent gene expression upon activation of Cp that may guard against overexpression of the EBNAs prior to the switch in promoter usage.⁶³⁴

EBNA-LP and EBNA-2 reach the level that is maintained in transformed B cells (LCLs) by 24 to 32 hours postinfection.¹⁷ By 36 hours the Wp and the upstream Cp EBNA promoters are both functional, resulting in rightward transcripts extending through at least 70% of the genome.^{17,379,494,534,898,902,1148,1150,1274,1275,1381,1383} LCLs transformed by a virus lacking the EBNA-2-responsive Cp element are biased toward Wp usage but not substantially impaired in transformation efficiency or different from wild-type virus infected cells in EBNA expression.¹⁵⁹⁹ Indeed, Cp-mediated transcription suppresses Wp.¹¹⁹⁰ Interestingly, deletion of the Wp -169- to -369-bp upstream control region, which affects both Wp and Cp activity, resulted in compensatory use of downstream copies of Wp and decreased transformation efficiency.^{1189,1601} The Wp promoter appears to be active in many cell types and has a region that is required for B-cell transformation that binds the

FIGURE 61.5. Schematic depiction of the Epstein-Barr virus (EBV) episome. The EBV episome is circularized through terminal repeats (TR). Shown are the transcripts, messenger RNAs (mRNAs), and major proteins in type III latent B-lymphocyte infection. Largely unique (U1 to U5) and internal (IR1 to 4) or terminal repeat DNA segments are indicated. The origin for latent infection EBV episome replication, oriP, is also indicated. Exons encoding EBV nuclear proteins (EBNA-1, -2, -3A, -3B, -3C, and -LP) or EBV integral latent membrane proteins (LMP 1, 2A, or 2B) are indicated by vertical lines radiating from the circular episome map. EBNA transcription is shown as it is first initiated from the IR1 or Wp promoter. In many infected lymphocytes, after expression of EBNA-LP and EBNA-2, the Cp promoter in U1 dominates EBNA transcription. Alternative polyadenylation and splicing result in expression of the various EBNA mRNAs. EBNA-LP is encoded by repeating exons from IR1 and two short unique exons from U2. The EBERs are two small, nonpolyadenylated RNAs. LMP1 is transcribed in direction opposite to the EBNAs, LMP2A and LMP2B, and EBERs. LMP2A has an upstream EBNA-2 response element, whereas LMP1 and LMP2B share the same EBNA-2 response element.

B-cell-specific BSAP/Pax5 activator protein.¹⁴⁵⁰ The Cp promoter also appears to be B-cell specific.²⁵⁹ Mutational analysis of the Wp and Cp promoters has suggested that transcription from Cp interferes with transcription initiation at the downstream Wp promoter.¹¹⁸⁹ Interestingly, deletion analysis has demonstrated that the Cp promoter is not essential for *in vitro* transformation of primary B lymphocytes by EBV.¹⁴¹¹

EBNA-2 up-regulates specific EBV and cell promoters and EBNA-LP potentiates EBNA-2 effects.^{2,534,1098,1349,1473,1518–1520,1524,1548–1550} Major viral targets of EBNA-2 include Cp, LMP1, LMP2B, and LMP2A promoters through a bidirectional enhancer element shared by the LMP1 and LMP2B promoters and an enhancer element in the LMP2A promoter.^{368,458,694,834,835,1357,1358,1473,1524,1578,1636} Interestingly, EBNA-LP has less co-activation effects with EBNA-2 on the EBV LMP2A promoter, the cell CD21, and HES-1 promoters.¹¹⁵³ The relative role of EBNA-LP in the EBNA-2-responsive CD23, c-fgr, and c-myc promoters has not been characterized.^{17,263,527,534,792,1098,1153,1518–1520,1598} EBNA-3A, EBNA-3B, EBNA-3C, and EBNA-1 do not reach levels seen in LCLs until 46 to 72 hours after infection, consistent with dependence on EBNA-2 and EBNA-LP up-regulation of the Cp promoter. Although EBNA-3A, EBNA-3B, EBNA-3C, and EBNA-1 mRNAs accumulate at very low levels, EBNA-3A, EBNA-3B, EBNA-3C, and EBNA-1 proteins are remarkably stable and expressed at high levels in LCLs. EBNA-3A, EBNA-3B, EBNA-3C, and EBNA-1 protein levels are positively affected by an internal ribosome entry site (IRES) in the U exon that is common to their mRNAs and by their intrinsic stability.^{99,359,658} Full steady-state LCL levels of EBNA-1 at 72 hours after infection ensure EBV episome transmission to progeny cells and further enhance transcription from promoters around oriP; oriP is an EBV DNA fragment that includes an EBNA-1-dependent enhancer and an EBNA-1-dependent replication origin.^{442,1215,1216,1404,1588} To regulate the promoter activities of Cp and Wp by EBNA-2; EBNA-3A, EBNA-3B, and EBNA-3C compete with EBNA-2 for binding to RBP-Jκ/CBF1.^{696,979,1228,1229} RBP-Jκ/CBF1 is a cellular protein that by binding to EBNA-2 is able to recruit the transcriptional activation function of EBNA-2 to DNA through its DNA sequence-specific binding function on the Cp enhancer.^{494,694,899,902}

Following initial EBV infection, EBV up-regulates c-myc and CD21 RNA and c-myc protein expression are increased at 16 to 24 hours after B-lymphocyte infection, soon after EBNA-2 and EBNA-LP are expressed.¹⁷ CD23 expression is delayed relative to CD21. Patches of LMP1 are detectable in B cells by 48 hours and LMP1 protein is at levels observed in LCLs by 72 hours.¹⁷ By 46 hours after infection 15% of cells are in S phase, and at 72 hours a substantial fraction of infected cells have divided.

By 72 hours EBERs are expressed in the cell nucleus. EBER 1 and EBER 2 RNAs are transcribed by cell RNA polymerase (pol) III, which is enhanced by EBNA-1.^{49,615,616,680,859,1124} The EBERs have intragenic control regions common to pol III transcripts and upstream Sp1, ATF, and TATA elements characteristic of pol II transcriptional sites.^{615,616} At steady-state levels in latently infected B lymphocytes, the EBERs are the most heavily transcribed and most abundant EBV RNAs. EBERs are estimated to accumulate at about 50,000 copies per cell nucleus.^{49,615–617,773,774,826}

In forms of latency other than latency III, where there is reduction in latent gene expression, this change is at least in part due to epigenetic mechanisms. In persistent infections, there is a down-regulation of latency 3 promoters and a switch to latency 1, 2, or 0. During latent infection, the EBV genome can undergo progressive methylation and condenses with nucleosomes.^{95,339,372,373,624,677,775,1323} Regulatory domains and genes involved in maintaining latent infection such as oriP tend to be undermethylated in latently infected cells relative to DNA that is expressed only in lytic infection.^{372,1032–1034,1104,1429} Extensive methylation of lytic genes and their regulatory elements probably helps to maintain latency by inhibiting lytic gene expression.¹⁴¹⁹ Treatment of latently infected cells with drugs that reduce DNA methylation increases the frequency of spontaneous activation to lytic infection.^{991,1230} Methylation of the EBNA-2 response element may be important for down-regulation of Cp promoter activity *in vivo* in some EBV-related malignancies.^{642,691,1231,1409} In latency 1, in which no other EBNA proteins are expressed, Cp/Wp promoter activity is inactivated and EBNA-1 is driven by an EBNA-1-specific promoter termed Qp that is located more than 50 kbp from Cp and Wp.^{1103,1272,1294,1295} Qp is a TATA-less promoter that is negatively regulated by two EBNA-1 binding sites downstream of the transcriptional initiation site.^{1272,1273} In addition, the transcription factor E2F can reverse EBNA-1-mediated repression of the Qp promoter by displacement of EBNA-1 from Qp by binding to two E2F-like sites that overlap the EBNA-1 binding sites.¹⁴⁰⁹ The Qp promoter is functional when introduced into a variety of cell types,^{1101,1274,1295} suggesting that Qp promoter activity may be constitutive. EBNA-1 is the only known negative regulator of Qp activity. In the absence of Cp- or Wp-mediated expression of EBNA-1, the Qp promoter is functional, thus ensuring expression of EBNA-1 to maintain the viral episome.¹¹⁰² Histone acetylation and methylation at essential promoter elements also contributes to the regulation of latent viral gene expression.^{13,197,293} EBV genomes are not randomly distributed in the nucleus but localize to perichromatic regions that are enriched for specific preferentially methylated and acetylated histones indicative of transcriptionally active regions.³⁰⁴ CTCF binding sites have also been identified in the EBV genome. CTCF is an 11-zinc finger nuclear protein that binds to diverse and long DNA sequences, thereby mediating long-range chromatin interactions. CTCF can function as an insulator of transcriptional enhancers and a regulator of genomic imprinting. Genome-wide studies have identified CTCF binding sites at several key regulatory elements in the EBV genome.^{197,198,1267} Studies analyzing CTCF binding at Qp found that viral mutants containing mutations in the CTCF sites near Qp were reduced in recovery of stable episomes from viral bacmids, as well as a decrease in Qp transcription initiation and an increase of histone and DNA methylation at the Qp initiation site.¹⁴³⁹ More recent studies have shown that differential expression of CTCF and DNMT1 and DNMT-3B are not critical for restricted latency. EBV mutants lacking the Cp CTCF binding site had sustained Cp activity relative to wild-type virus, but transition to latency 1 was observed, indicating that CTCF contributes to the establishment of restricted latency but is not absolutely required.⁶³⁵ As well as acting as an insulator to silence EBV gene expression, CTCF binding to the EBV genome may anchor the genome to the nuclear matrix and

direct specific chromatin architectures that can mediate alternative promoter targeting by the OriP enhancer.¹⁴³⁸

More recent studies have shown that cells latently infected with EBV encode additional proteins as well as miRNAs compared with the limited repertoire of genes originally identified. In particular, weak Wp activity can drive the expression of BHRF1. In 15% of endemic Burkitt lymphomas (BLs), a transformation-defective EBNA-2–deleted virus was selected⁷³⁷ and infection was associated with activation of the Wp latent promoter with broadening of latent protein expression beyond that typically seen in latency I.^{737,739,740} This finding led to the discovery that BHRF1 and BALF1 are expressed in B cells immediately following infection²³ and BHRF1 transcripts can be detected at low levels in LCLs long term.⁷³⁸ Overall, these findings indicate that the four patterns of latent gene expression that have been described should be used only as a guide in subdividing types of EBV latency, because other viral genes may also be expressed. EBV genes newly identified as expressed in EBV latent infections will be discussed more fully after the functions of well-recognized latency-associated genes are described.

Translation: EBV Gene Products Associated With Latency

EBNA-1

EBNA-1 (Fig. 61.6A) associates with chromosomes during mitosis^{469,492,544,1117,1160,1174} and supports replication and stable maintenance of plasmids in human cells via a latent origin termed *oriL*.^{1587,1588} *OriP* consists of two functional elements separated by 1 kbp, the dyad symmetry (DS) element and the family of repeats (FR)^{1209,1216} (Fig. 61.6B). Interaction of EBNA-1 with the specific sequence *oriP* within the viral genome enables the viral genome to persist as an episome in latently infected LCLs.^{27,211,227,947} EBV *oriP* contains multiple copies of an 18-bp EBNA-1 recognition sequence, which is clustered in two noncontiguous functional elements, the family of repeats and the DS element⁹⁴⁷ (Fig. 61.6B). The DS element contains four EBNA-1 binding sites, a 65-bp region of dyad symmetry, and is the site for initiation of DNA replication.^{310,947,1105,1106,1171,1209} Within *oriP*, FR is an EBNA-1–dependent enhancer; six to seven copies are essential for enhancer function.^{1216,1566} The FR, but not DS, is important for the localization of the EBV genome in perichromatic regions that are enriched for histone methylation marks that are hallmarks of transcriptionally active regions.³⁰⁴ The separate DS has four copies and is the origin for episome DNA synthesis.^{441,1566} Telomere repeat binding factor 2 (TRF2), TRF2-interacting protein hRap1, and the telomere-associated poly(adenosine diphosphate [ADP]-ribose) polymerase bind to nonamers in DS and the binding is EBNA-1 dependent.²⁹⁹ A minor component, termed Rep*, is a nearby EBNA-1–independent origin for DNA synthesis.⁷⁷⁷ Three copies of Rep* can complement deletion of DS.⁷⁷⁷ Cell DNA origins can also replace the DS element.^{807,992} The function of EBNA-1 and *oriP* plasmid maintenance in rodent cells requires replacing DS with a rodent DNA replication origin.⁸⁰⁶

EBNA-1 binds as a dimer, and both the DNA binding and dimerization domains map near the carboxyl terminus of the protein^{27,79,112,211} (Fig. 61.6B). The repeat unit of *oriP* acts as an enhancer in the presence of EBNA-1, which is important for latent gene transcription from the Cp promoter.^{66,442,1157,1171}

In addition, lower-affinity EBNA-1 binding sites near the Qp promoter are important for the expression of EBNA-1 in the non-latency 3 programs.^{3,26,59,570,1101,1295} The transcriptional activation of EBV latent genes by EBNA-1 is essential for EBV transformation of primary B cells.²⁴

The structure of EBNA-1 bound, and not bound, to DNA has been solved^{79,112,113} (Fig. 61.6C,D). The EBNA-1 dimer is composed of multiple domains. The dimerization domain extends from amino acid 504 to 604.^{79,112,113} Amino acids 459 to 503 include a helix that projects into the major groove and an extended chain that moves along the minor groove and makes all the sequence-specific contacts with the DNA of the binding site. Amino acids 477 to 489 form a helix, which is oriented perpendicularly to the axis of the DNA, and amino acid 477 contacts the DNA. Amino acids 490 to 504 form an extended loop that connects the helix to the first β strand of the core β barrel. Amino acids 461 to 469 form an extended chain that tunnels along the minor groove near the outside of the binding site, wraps around the DNA toward the center of the binding site, and exits between the second and third bases away from the middle of the binding site. These amino acids appear to provide most of the sequence-specific DNA contacts. Amino acid 469 is connected to amino acid 477 by a loop that traverses along and forms multiple hydrogen bonds with the DNA phosphate backbone.

EBNA-1 binding to its cognate sequence appears to be cooperative,^{1030,1209,1406} suggesting that either EBNA-1 molecules interact cooperatively in binding to DNA or that the DNA template is modified as a consequence of initial EBNA-1 binding. Crystallography, electron microscopy, and biochemical data indicate that EBNA-1 binding to the family of repeats and the DS element results in high-order structures that lead to bending and distortion of the DNA duplex.^{421–424,1013,1121} Early findings suggested that cellular proteins were required for episome maintenance and not required for enhancer activity, because EBNA-1 binding to the family of repeats enhances transcription in mouse or human cells, whereas EBNA-1 promotes episome replication only in primate cells.⁸⁰⁶ Recent studies have identified a number of cellular proteins that likely participate in EBV genome replication. Subunits from the cellular origin recognition complex (ORC) and the minichromosome maintenance (MCM) complex associate with the DS element of *oriP*, suggesting a role for these factors in the initiation and licensing of EBV genome replication.^{199,309,701,1300} It is not known how ORC is recruited to the DS element. EBNA-1 may facilitate ORC recruitment to DS by disrupting nucleosomes formed at the DS element, allowing ORC access to DNA.^{56,1631} EBNA-1 binding to its recognition sites *in vitro* is greatly stimulated by binding to the cellular deubiquitinating enzyme, USP7. USP7 can form a ternary complex with DNA-bound EBNA-1¹²⁸⁴ and is part of a histone deubiquitinating complex. Other proteins that may have roles in EBNA-1 function include Cdt1,³⁰⁹ TAF-1 (β isoform),¹⁵²⁸ TRF2,^{298,299,897} TRF2-interacting protein hRap1,^{298,299} and the telomere-associated poly(ADP-ribose) polymerase (Tankyrase).^{298,299} EBNA-1–binding protein 2 (EBP2) is important for interactions between EBNA-1 and chromosomes in metaphase and association with metaphase chromosomes.^{712,713,1078,1339} Poly(ADP-ribose) polymerase (PARP) is an abundant, chromatin-associated, nicotinamide adenine dinucleotide (NAD)-dependent enzyme that functions in multiple

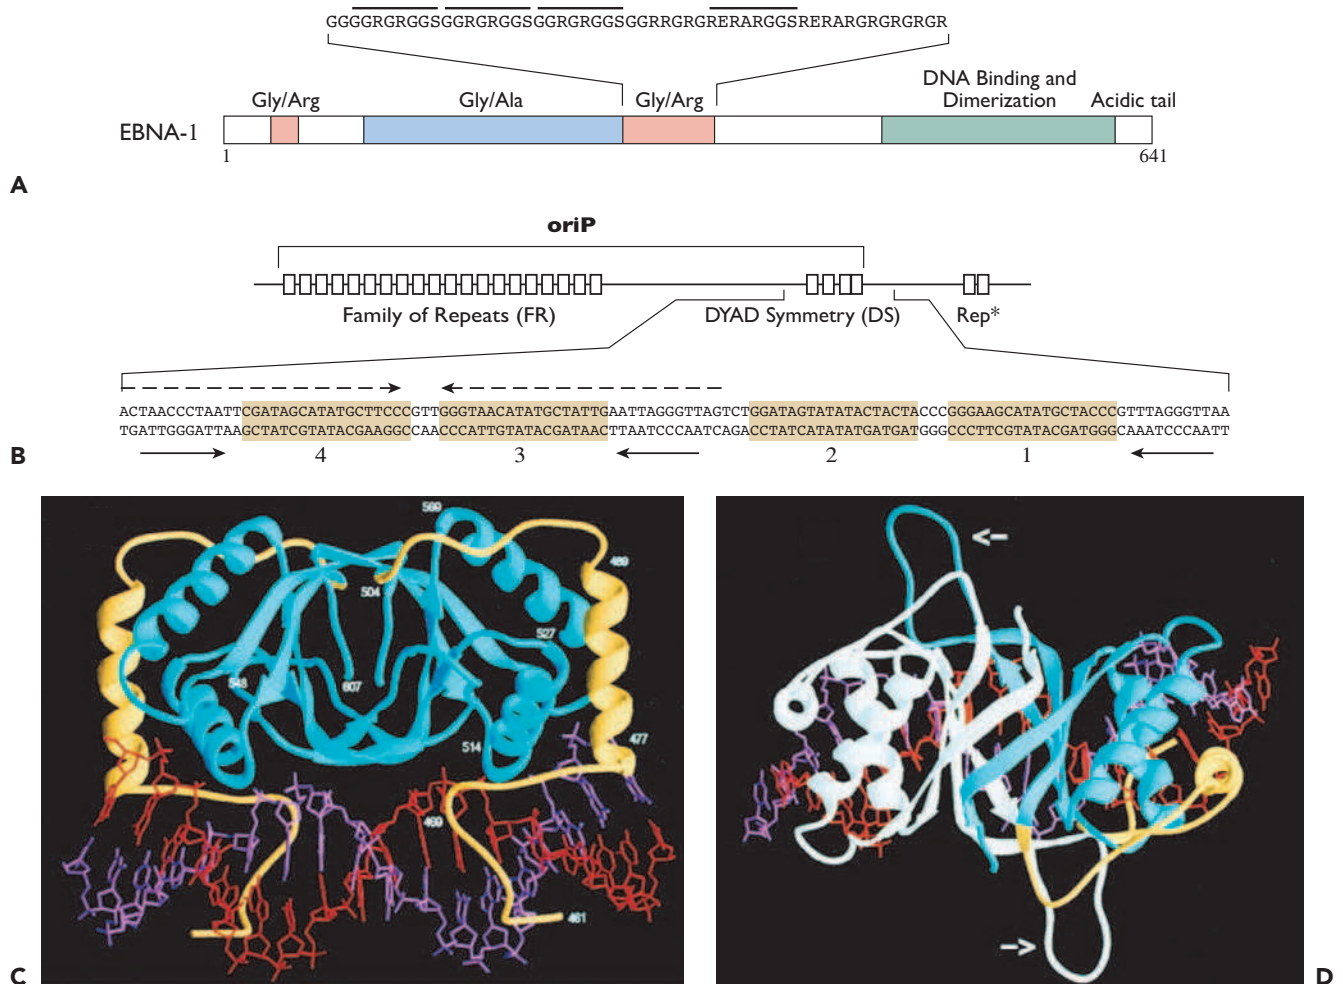

FIGURE 61.6. Structure of Epstein-Barr virus nuclear antigen 1 (EBNA-1) bound to DNA, schematic of the oriP DNA arrangement, and EBNA-1 functional domains. **A:** Important EBNA-1 functional domains. The amino terminal Gly/Arg domain is important for replication, segregation, and transcription and has been shown to bind P32/TAP. The central Gly/Arg sequence is also important for replication, segregation, and transcription. This domain has been shown to bind a variety of cell proteins including EBP2, Nap1, p32/TAP, MDF1, PRMT1, and PRMT5. The DNA binding and dimerization domain at the C-terminus of EBNA-1 is essential for all known functions of EBNA-1 including replication, segregation, and transcription. Regions outside these domains of EBNA-1 are generally thought to be nonessential but have been shown to bind cellular proteins including Tankyrase and USP7. **B:** The oriP family of repeats (FR) and dyad symmetry (DS) elements are shown with an expanded view of the nucleotide sequence of DS with the EBNA-1 binding sites 1 to 4. The nonamer repeats (*solid arrows*) and the 65-base-pair dyad symmetry (*broken arrows*) are also shown. EBNA-1 binding sites are shown as boxes with the dyad present in DS denoted by the head-to-head arrows. The Rep* element is located 240 bp downstream of DS. **C:** EBNA-1 bound to DNA with a ribbon diagram showing the core domain, which contains residues 504 to 607 from each monomer, in blue. The flanking domains from each monomer are shown in yellow. The amino acids are numbered according to their position in the full-length EBNA-1 protein derived from B95-8. **D:** A view down the noncrystallographic axis that shows one monomer in white and the other monomer in the same color scheme as used in C. The proline loops are indicated by the arrows. (From Bochkarev A, Barwell JA, Pfuetzner RA, et al. Crystal structure of the DNA-binding domain of the Epstein-Barr virus origin-binding protein, EBNA1, bound to DNA. *Cell* 1996;84[5]:791–800, copyright © 1986 Elsevier.)

chromosomal processes, including DNA replication and chromatin remodeling, and overall negatively affects EBNA-1 function.¹⁴³⁷

An important feature of EBNA-1 is its ability to act as a bridge coupling the EBV genome to host chromosomes. Multiple RG rich EBNA-1 residues are required for EBNA-1 binding to host chromosomes.^{641,974,1078,1339,1560,1561} This

interaction is also mediated by proteins that associate with EBNA-1 such as EBP2^{713,1339} or through direct interactions of EBNA-1 with cellular DNA as suggested by EBNA-1 glycine- and arginine-rich regions that resemble AT hooks.¹³¹³ More recently, these regions have been shown to have a strong preference for G-quadruplex RNA; G-quadruplex RNA-interacting drugs block EBNA-1 functions, suggesting a role of RNA

binding for the function of EBNA-1.^{1107,1108} Further studies are clearly needed to fully understand the mechanism of EBNA-1 binding to cellular DNA. Cellular chromatin and chromosomal proteins such as high mobility group I (HMG-I) amino acids 1 to 90 or histone H1 can functionally substitute for the EBNA-1 regions responsible for host chromosome binding in enabling chromosome binding and long-term episome persistence.^{641,1313} EBNA-1 is a serine phosphoprotein.^{544,1160,1174} Functionally, serine phosphorylation is important for genome segregation,^{329,825,1340} and interestingly, roscovitine, a selective inhibitor of CDK1, blocks EBNA-1 serine phosphorylation, nuclear localization, transcription, and episome maintenance.⁷⁰⁸

EBNA-1 has been proposed to have a role in cell growth and survival. Two studies using EBNA-1 transgenic mice indicate a greater incidence of lymphoma in these mice alone^{1543,1544} and in cooperation with Myc.³²⁷ However, in two more recent studies, there was no increased incidence of lymphoma. The EBNA-1 transgenic mice did not display any gross phenotypic differences when compared to littermate controls.^{709,710} Other studies indicate that EBNA-1 induces genomic instability and a DNA damage response.^{499,500} However, EBNA-1 is not a dominant transforming gene of EBV because EBNA-1 deletion does not compromise immortalization of B cells by EBV or outgrowth in severe combined immunodeficiency (SCID) mice, but only the efficiency of transformation because the EBV genome must integrate into the host genome to allow genome persistence in the absence of EBNA-1 expression.⁶³⁷ The contribution of EBNA-1 to B-cell immortalization, outside of activation of EBV latent genes²⁴ and maintaining the EBV genome in infected cells, appears to be limited in comparison with other latent EBV proteins such as LMP1, EBNA-2, EBNA-LP, or EBNA-3C that when mutated have more dramatic effects on EBV transformation of B cells (see relevant sections within this chapter).

Despite having a limited role in EBV-mediated transformation of B cells, EBNA-1 may have importance in the development of EBV-associated cancers. EBNA-1 may alter cell growth by enhancing expression from EBNA-1-binding sequences in cell DNA or by interaction with cell proteins (see earlier). Expression of a dominant negative form of EBNA-1, which blocks EBNA-1 interaction with cognate DNA, in an LCL with integrated EBV DNA resulted in no change in cell growth or virus or cell gene expression,⁷⁰⁷ consistent with observations that EBNA-1-negative LCLs do not differ in growth from wild-type LCLs.⁶³⁷ Furthermore, EBNA-1 strongly enhances transcription from an episome with an oriP FR near a promoter but has much less effect on the same elements integrated into cell DNA, unless their endogenous expression level is minimal.^{707,743} Additionally, expression of EBNA-1 has little effect, or a negative effect, on the growth of EBV-negative BL cells.⁷⁴² On the other hand, EBNA-1 partially protects EBV-negative BL cells from the apoptotic effects of p53 overexpression,⁷⁴² and inhibition of EBNA-1 in EBV-positive BL cells can induce apoptosis,⁷⁴² consistent with EBNA-1 or another EBV genome product affecting EBV-positive BL cell survival. Also, EBNA-1 can associate with Mdm2 and the p53 ubiquitin specific protease USP7 and could affect p53 stability, although the affinity of EBNA-1 for USP7 is less than that of p53.¹²⁸³

High-affinity EBNA-1-binding sequences have not been identified in cell DNA.⁶⁰⁹ More recently, a number of studies

using transcription profiling, chromatin immunoprecipitation followed by microarray hybridization (ChIP-Chip), and ChIP combined with deep sequencing (ChIP-Seq) have identified a large number of potential cellular targets of EBNA-1.^{166,326,932,1371}

Many studies have been done analyzing the potential of EBNA-1 to alter the expression of cellular genes that may provide a growth advantage to cells expressing EBNA-1. Survivin, an apoptosis suppressor protein, is up-regulated by EBNA-1.⁹³⁶ EBNA-1 modulation of host cell gene transcription affects the STAT1 and transforming growth factor- β (TGF- β) signaling pathways.¹⁵⁵³ ChIP-Seq has been used to identify cellular sites bound by EBNA-1. A cluster of binding sites were identified on chromosome 11 and EBNA-1 bound close to the transcriptional start site of a large number of cellular genes.⁹³² The significance of these findings needs to be determined.

EBNA-2

Early studies identified a transformation-incompetent but replication-competent laboratory strain of EBV, P3HR-1, in BL cells from a culture of Jijoye BL tumor cells.^{583,584,1023} The search for the biochemical basis of the nontransforming phenotype led to the discovery and characterization of EBNA-2.^{253,282,283,566,758,772,773,1185,1200} Transfection of cells infected with the P3HR-1 with cloned wild-type EBV DNA that spanned the deletion resulted in homologous recombination and restoration of transformation competence.^{252,253,523} Transfection with cloned EBV DNA fragments deleted for part of EBNA-2 ORF or containing a stop codon one-third of the way into the EBNA-2 ORF failed to restore transforming ability. Recombinant EBVs with a nontransforming EBNA-2 mutation could also be recovered by infection of EBV-negative BL cells.⁹⁷² EBNA-2 differs extensively between EBV types 1 and 2, and this results in a differential ability to cause LCL outgrowth.^{253,282,1222} Restoration of the P3HR-1 deletion with type 1 or type 2 EBNA-2 indicates that EBNA-2 is the principal determinant of efficient transformation of primary B lymphocytes.²⁵³ Primary B lymphocytes infected with type 2 P3HR-1 EBV harboring type 1 EBNA-2 DNA proliferate into LCLs as rapidly as lymphocytes transformed by type 1 EBV strains. In contrast, recombination of cloned type 2 EBNA-2 DNA in place of the P3HR-1 deletion results in deficient transformation, characteristic of type 2 EBV. Interestingly, studies have shown that type 1 EBNA-2 induces more cell genes including CXCR7, suggesting that this may be in part why type 1 EBNA-2 causes more robust LCL outgrowth.^{168,938}

EBNA-2 is a specific transactivator of cell CD23, CD21, c-fgr, and c-myc and EBV LMP1, LMP2A, LMP2B, and Cp promoters. EBNA-2 is a transactivator that has no DNA-binding activity, but rather is brought to promoters that contain EBNA-2 response elements by cellular DNA-binding proteins. EBNA-2 stably associates with the cell sequence-specific DNA-binding protein RBP-J κ /CBF1.^{494,694,899,902} EBNA-2 can transactivate through a multimerized RBP-J κ site^{899,902} and is at least partially dependent on RBPJ κ sites for transactivation of LMP1 and LMP2B,^{694,834} LMP2A,¹⁶³⁷ Cp,⁶⁹¹ CD21,⁹⁶³ and CD23⁸⁹⁹ promoters. Other elements important for EBNA-2 responsiveness include the PU.1^{694,834,1578} and CRE binding site in the LMP1 promoter¹³⁵⁹ and the AUF1 binding site in the Cp and CD21 promoters.^{433,1459} Based on the similarity to EBNA-2 with an activated Notch, the cellular binding partner

of RBP-J κ /CBF1, cellular genes that are activated by EBNA-2 have been globally studied.^{958,1305,1384,1628} Studies using CHIP-seq and an analysis of long-range chromosomal interactions (HiC) indicate that EBV utilizes intrinsic B-cell transcriptional programs mediated by EBNA-2 and RBP-J κ /CBF1 to achieve B-cell immortalization by targeting H3K4me1-modified, nucleosome-depleted, nonpromoter sites to drive proliferation of resting B cells by activation of cell growth genes.¹⁶³⁰ In EBV LCLs, constitutive Notch signaling does not replace EBNA-2 function to maintain B-cell proliferation.^{475,598} Partial rescue of proliferation could only be achieved by co-expressing LMP1 independently of EBNA-2 or by expressing activated Notch at high levels.^{475,598} Further studies based on this observation have shown that EBNA-2 and activated Notch induce pro-apoptotic cellular genes, whereas EBNA-2 only up-regulates antiapoptotic genes.⁷⁹³

Recombinant EBV genetic analysis of EBNA-2 using marker rescue of primary B-lymphocyte transforming activity in the background of EBNA-2–deleted P3HR-1 EBV identified three essential EBNA-2 domains (Fig. 61.7), which are also critical for LMP1 and Cp promoter up-regulation. The essential domains correspond to a requirement for N-terminal amino acids 1 to 58 or 97 to 210,^{252,253,1577} which mediate homotypic association⁵³⁵; amino acids 280 to 337,^{252,536,1467,1578} which mediate interaction with RBP-J κ /CBF1 through amino acids PWWP^{494,559,1578} and SKIP¹⁶³²; and amino acids 420 to 464,^{244,252,1467} which are an acidic activation domain.^{244,250,252}

In activating transcription through RBP-J κ , EBNA-2 mimics a constitutive Notch receptor. The WWP sequence in EBNA-2 is similar to the WFP sequence in the Notch receptor intracellular domain that normally mediates tight association with RBP-J κ in up-regulating HES-1 in tissue development.¹⁴²³ An EBNA-2 WW to SS mutation ablates EBNA-2 up-regulation of the Cp promoter, reduces LMP1 promoter activation by 50%, and ablates EBV transformation of primary B lymphocytes

into LCLs.¹⁵⁷⁸ A subtle EBNA-2 WW to FF mutation also substantially reduces EBNA-2 transactivation of the Cp and LMP1 promoters.¹⁵⁷⁸

Once near promoter sites, the EBNA-2 acidic activating domain recruits basal and activation-associated transcription factors including TFIIB, TAF40, TBP, RPA70, TFIIF, and CBP/P300 (Fig. 61.7).^{1464–1466,1527} In B lymphocytes, but not CHO cells, the EBNA-2 acidic domain is nearly as strong in activation of basal reporter constructs with multiple upstream Gal-4 binding sites as the core VP16 14 amino acids, while the corresponding EBNA-2 14 amino acids have only 25% of the VP16 activity.²⁵⁰ Despite their greater activity in transient assays, the VP16 14 amino acids can substitute for the corresponding EBNA-2 amino acids in primary B-lymphocyte conversion to LCLs, when expressed in an EBV recombinant.²⁴⁴ Much of the EBNA-2 acidic domain is complexed with a cell nuclear protein, p100, that has co-activating effects with EBNA-2.¹⁴⁶⁵ p100 is a scaffolding protein for the acidic domain, for TFIIE, for c-myc, and for PIM-1.^{1205,1465} Efficient assembly of multiple transcription factors at promoter sites appears to require multiple EBNA-2 acidic domains, because two separate EBNA-2 domains mediate homotypic association.⁵³⁵

EBNA-2 is associated with nucleoplasm, chromatin, and nuclear matrix fractions and localizes to large nuclear granules.^{566,1160} EBNA-2 is phosphorylated on serine and threonine residues and may undergo significant posttranslational modification other than phosphorylation, because the size of the nascent protein is 10 kD smaller than stable intranuclear EBNA-2.^{484,1521} Numerous studies have suggested a role of phosphorylation in EBNA-2 function. Serine 243 is a target of both BGLF4 protein kinase and cdc2/cyclin B1 kinase and phosphorylation results in suppression of EBNA-2 activity.^{1614,1615} Although not essential for transformation or transcriptional activation, the domain that is carboxyl-terminal to the polyprolines has also been implicated in

FIGURE 61.7. Schematic depiction of Epstein-Barr virus nuclear antigen (EBNA)-2 domains. EBNA-2 contains a domain that interacts with the cellular sequence-specific DNA binding proteins RBP-J κ and PU.1 to bring it to specific promoters, including the latent membrane protein 1 (LMP1) promoter. The EBNA-2 N-terminus has two domains that can mediate homotypic association with other EBNA-2 molecules. Within this region there is an interactive domain for Nur77. The poly-proline (PP) and poly-arginine-glycine (RG) as well as the activation domain (AD) are shown. The tryptophan-tryptophan-proline (WW) sequence in EBNA-2, which is similar to a sequence in the Notch receptor intracellular domain that normally mediates tight association with RBP-J κ in up-regulating HES-1 in tissue development, is shown. Mutation of this sequence ablates EBNA-2 transactivation.¹⁵⁷⁸ The EBNA-2 acidic domain (AD) interacts with TAF40, TFIIB, TFIIF, TFIIE, TBP, P300/CBP, p100, and EBNA-LP in stimulating transcription. The EBNA-2 acidic domain is extensively associated with p100, which is a scaffolding protein for c-myc and PIM-1. Nine conserved regions of EBNA-2 (bars above the protein) have been identified by comparing type 1 and type 2 EBNA-2 with those from related lymphocryptoviruses (LCVs) that infect nonhuman primates.⁹⁰³

interactions with human SNF5/INI1 and the DEAD box protein DP103.^{502,1557,1558} DP103 is a DEAD box protein with RNA helicase activity that appears to have transcriptional repressive effects. SNF5/INI1 and DP103 interact with EBNA-2 amino acids 112 to 344 in yeast two-hybrid screens,^{1557,1558} and the interaction of EBNA-2 with SNF5/INI1 has been mapped to several sites within EBNA-2 including a casein kinase II (CKII) phosphorylation site.⁸²¹ Finally, Nur77 associates with EBNA-2 via conserved region 2 (CR2) and the resulting interaction can block apoptosis by etoposide and 5-fluorouracil (Fig. 61.7).^{847,848}

The EBNA-2 RG repeat domain has an unusual, partly understood role in EBNA-2 activation and EBNA-LP co-activation (Fig. 61.7).^{1148,1150,1467} EBV recombinants deleted for the RG domain are deficient in transforming primary B cells to LCLs and hyperactivate the LMP1 promoter in transient transfection assays. The RG repeat binds histone H1, EBNA-1, and nucleic acids, especially poly(G). The strong interaction of the EBNA-2 RG domain with histone H1 is consistent with the effect of the RG domain deletion in releasing EBNA-2 from the chromatin to the nucleoplasm.¹⁴⁶⁷ These data are most compatible with a model in which the RG domain modulates EBNA-2 interactions with chromatin in transcriptional regulation. Studies with the EBNA-2 acidic domain provided the key link between acidic domains and p300/CBP recruitment to promoters. More recently, genome wide studies have found EBNA-2 to have evolved to enter approximately 5,000 enhancer elements throughout the human genome in B lymphocytes to up regulate myc and other cell genes necessary for B cell growth and survival.¹⁶³⁰

EBNA-LP

EBNA-LP is composed of several 22- and 44-amino acid segments encoded by IR1 W1 and W2 exons and 11- and 34-amino acid segments encoded by Y1 and Y2 exons (Fig. 61.8A). Because the number of IR1 repeats varies among EBV isolates, EBNA-LP frequently varies in size in different EBV isolates or even different progeny of the same virus.^{313,391,1521}

The 44-amino acid domain encoded by W2 exons has two runs of basic amino acids, RRHR and RRVRRR, which enable EBNA-LP nuclear localization (Fig. 61.7B).^{1154,1425} EBNA-LP is phosphorylated at multiple sites, probably at least once within each 44-amino acid repeat, because the number of iso-electric forms varies with the W1W2 exon repeat number.¹¹⁶⁰ The number of repeats has a direct effect on the transforming ability, with optimum transforming function observed with viruses containing five repeats.¹⁴⁵² EBNA-LP is phosphorylated on serine residues and *in vitro* is a substrate for both casein kinase II and the cyclin-dependent p34cdc2^{783,1598} and the EBV-encoded kinase BGLF4.⁷²¹ This phosphorylation occurs in a cell cycle stage-specific manner, with the protein being hyperphosphorylated in late G2 consistent with a role for p34cdc2 in phosphorylation of EBNA-LP.^{783,1160}

EBNA-LP is transcribed along with EBNA-2 at the initiation of EBV infection in primary B cells and cooperates with EBNA-2 in the activation of virus and cell gene expression.^{17,534,1098,1154,1349} Co-activation is evident in transient expression assays with artificial LMP1 promoter constructs and with endogenous LMP1 expression in EBV-infected BL cells that are otherwise in latency 1 and fail to express LMP1 until EBNA-2 and EBNA-LP are co-expressed by gene transfer. Association of EBNA-LP with EBNA-2 is evident when the two proteins are expressed and purified from bacteria and incubated under physiologic conditions or when EBNA-LP deleted for its C-terminal 11 amino acids is expressed with EBNA-2 in human B cells.¹¹⁴⁸ EBNA-LP does not significantly associate with EBNA-2 in LCLs.¹¹⁴⁸ However, EBNA-LP can bind to and co-activate through the EBNA-2 acidic activating domain or through an EBNA-2 N-terminal 58-amino acid domain.¹¹⁵⁰

EBV recombinant genetic analyses of EBNA-LP have focused on the C-terminal two exons, because mutations in the repeating exons of EBNA-LP are more difficult to construct. Specific deletion of DNA encoding the C-terminal two exons or placement of a nonsense codon at the beginning of the last two exons resulted in EBV recombinants that are deficient in

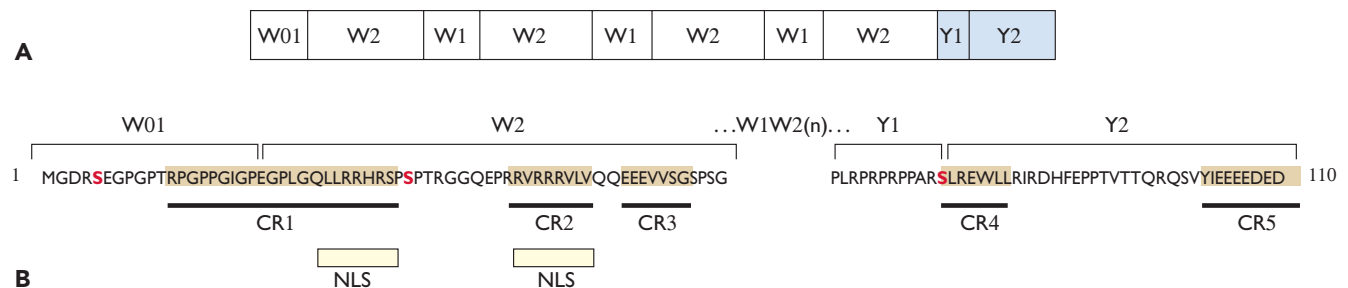

FIGURE 61.8. Schematic diagram of the repeat and unique exon and domain structure of Epstein-Barr virus nuclear antigen leader protein (EBNA-LP). The exons of EBNA-LP are derived from the BamHI W and Y fragments with initiation of transcription from Wp or Cp. **A:** The EBNA-LP AUG is generated by a unique alternative 5' splicing event. The W1 and W2 regions are repeats of 22 and 44 amino acids, respectively. This EBNA-LP repeat domain co-activates transcription mediated by the EBNA-2 acidic domain. The unique C-terminus of EBNA-LP consists of Y1 and Y2, which is dispensable for EBNA-2 co-activation and modulates EBNA-LP function. **B:** Amino acid sequence of the unique W01 exon and the W2, Y1, and Y2 exons. A single W1/W2 repeat is shown. Also shown are serines that are phosphorylated and conserved regions (CRs) in EBNA-LP proteins encoded in EBV and the nonhuman primate lymphocryptoviruses (LCVs).

primary lymphocyte transformation into LCLs.^{523,970} In two series of experiments that resulted in many wild-type EBV recombinant LCLs, only two LCLs were obtained that were infected with recombinants that were deleted for the C-terminal two exons, and these LCLs were deficient for growth. Transfection of one of these LCLs with an expression vector for wild-type EBNA-LP enabled the LCLs to grow out more rapidly under selection than control LCLs.¹⁸ Despite growth of infected primary B cells on fibroblast feeder layers, the frequency of derivation of EBNA-LP nonsense recombinant transformed LCLs was less than 5% of wild-type recombinants, and cell growth was slower than with wild-type recombinants. One mutant recombinant-infected LCL was obtained that had wild-type growth characteristics, and that LCL proved to be infected with a revertant.⁹⁷⁰ Passage of the deletion or nonsense EBNA-LP recombinants into other primary B lymphocytes further confirmed the reduced transformation phenotype.⁹⁷⁰ Infection of multiple primary B cells with higher-titer mutant recombinant virus enabled better outgrowth of LCLs infected with the mutant EBNA-LP EBV recombinants, presumably because of cross-feeding among the multiple mutant EBV-infected cells.⁹⁷⁰ There was no difference in latent EBV gene expression other than the absence of wild-type EBNA-LP. The mutant virus-infected LCLs were more highly differentiated toward immunoglobulin secretion, compatible with the possibility that wild-type EBNA-LP inhibits differentiation. In other experiments, transient expression of EBNA-LP and EBNA-2 in primary B cells co-stimulated with gp350 resulted in induction of cyclin D2.¹³⁴⁹ As described earlier, EBNA-LP potentiates EBNA-2-mediated transcription from the Cp and LMP1 promoters in transient transfection assays with reporter constructs and also co-activates EBNA-2 up-regulation of LMP1 expression in type 1 EBV-infected BL cells. Although EBNA-LP did not further co-activate CD21, LMP2A, and HES-1 promoters with EBNA-2—indicating promoter specificity in EBNA-LP co-activation,¹¹⁵³ EBNA-LP co-activation with Gal4-EBNA-2 in BL cells indicates that promoter specificity is somewhat relaxed.¹¹⁵⁰ Overall, EBNA-LP has a key role in up-regulating viral and cellular gene expression critical for LCL outgrowth, which is likely to be its primary role in EBV conversion of primary B cells to LCLs.

The unique 3' exons of EBNA-LP encode 11- and 34-amino acid C-terminal domains. While the repeating exons are efficient co-activators, addition of 11 or even 35 of the C-terminal residues results in nearly complete loss of co-activating effects where as, addition of the entire 45 C-terminal amino acids restores wild-type co-activation. These data indicate that the first 35 C-terminal amino acids have a strong negative regulatory effect on co-activation and the last 10 amino acids effectively silence the negative regulatory effect.^{534,1148} The negative effect of the stop codon mutation that prevented expression of the last 45 amino acids on primary B-lymphocyte transformation⁹⁷⁰ is evidence of the importance of this complex regulatory domain for efficient lymphocyte growth transformation. Differential phosphorylation of EBNA-LP by p34 cdc2 or casein kinase II may be important in the natural regulatory effects of the C-terminal domain.

An effect of EBNA-LP on retinoblastoma protein (Rb) and p53 has been suggested based on *in vitro* biochemical interactions and co-localization with Rb.¹⁴¹⁸ However, EBNA-LP is not associated with Rb family proteins or p53 in cell lysates

and does alter Rb- or p53-mediated transcription.⁶⁵⁷ Expression of EBNA-LP in transgenic mice had no discernible effect on development or tumor incidence.⁶³² The EBNA-LP transgenic mice died of heart failure, which is likely to be due to a toxic effect of EBNA-LP expression or an insertion site effect.⁶³² Immunoprecipitations of EBNA-LP from B lymphoblasts have resulted in the identification of the DNA-PK catalytic subunit, an AKAP 95 homolog, HA95, HSP72, and HSP27 as EBNA-LP-associated proteins.^{526,630,784,971} EBNA-LP associates at a very high level with HA95 in B cells and is also associated with DNA-PK, probably through HA95.⁵²⁶ HA95 appears to mediate EBNA-LP co-activation by heterodimerizing with EBNA-LP and removing NCoR and HDACs from matrix associated deacetylase bodies and freeing chromatin from repressors.⁵²⁷ EBNA-LP is partially localized in the cytoplasm and more often associated with the nuclear matrix fraction than other EBNA.¹¹⁶⁰ HSP72 up-regulates EBNA-LP co-activation with EBNA-2.¹¹⁴⁹ In immune microscopy of LCLs or of non-EBV-infected BL lymphoblasts in which EBNA-LP is expressed alone by gene transfer, EBNA-LP localizes to promyelocytic leukemia (PML) nuclear bodies.^{1417,1521} Sp100A, a PML nuclear body-associated protein, is another EBNA-LP-interacting protein.⁹⁰¹ EBNA-LP interacts with and displaces Sp100 from PML nuclear bodies.⁹⁰¹ Sp100A mutants deleted for the PML targeting domain, which is also the domain that interacts with EBNA-LP, can co-activate EBNA-2 independent of EBNA-LP, suggesting that displacement of Sp100A from PML nuclear bodies is an important EBNA-LP function.⁹⁰¹ Deletion of the HP1 α interaction domain in Sp100A prevents Sp100A co-activation, suggesting that EBNA-LP function may in part involve chromatin modification.⁹⁰¹ Studies in support of this have shown that EBNA-LP interacts with HDAC4 and 14-3-3 and sequesters HDAC4 in the cytoplasm. More recent studies have shown that isoforms of EBNA-LP smaller than 42 kD shuttle between the nucleus and cytoplasm.¹¹⁷⁸ Isoforms larger than 62 kD have no detectable nuclear-cytoplasmic shuttling activity and retain co-activation function. Moreover, the ability to interact with HDAC4 and shuttle between the nuclear and cytoplasmic compartments is not sufficient to mediate the co-activation function.⁹⁰⁴ Finally, EBNA-LP associates with NCoR and dismisses NCoR, NCoR and RBPJ, or NCoR, RBPJ, and EBNA-2 from matrix-associated deacetylase (MAD) bodies, which increases gene expression.¹¹⁷⁹

EBNA-3A, EBNA-3B, and EBNA-3C

The EBNA-3 genes are tandemly placed in the genome (Fig. 61.5), are collinear distant homologues, are transcribed under control of the far upstream latency 3 Cp or Wp EBNA promoters, share a U exon splice with EBNA-1, have individual splice acceptor sites that compete with EBNA-1, and have short and long exons, and have individual downstream polyA sites.^{65,115,116,564,692,748,1159,1161,1274,1275} LCLs have very few copies of each EBNA-3 mRNA. EBNA-3A, EBNA-3B, and EBNA-3C have repeating oligopeptides near their C-termini, which serve as unusual examples of domain amplifications within ORFs that are amplified from a common progenitor. The type 1 EBNA-3A, EBNA-3B, and EBNA-3C are 944, 938, and 992 amino acids, respectively (Fig. 61.9A).¹³⁴⁶ The type 2 EBNA-3A, EBNA-3B, and EBNA-3C proteins are 925, 946, and 1,069 amino acids and are 84%, 80%, and 72% identical to their type 1 counterparts, respectively.¹²⁷⁸

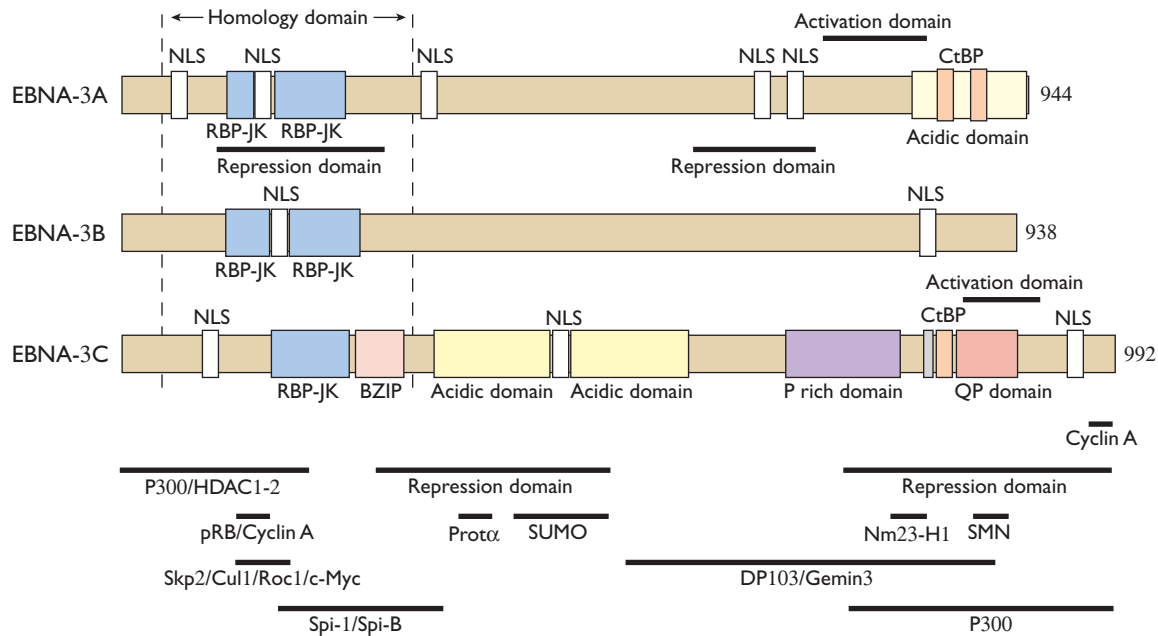

FIGURE 61.9. Schematic diagram of the Epstein-Barr virus nuclear antigen (EBNA)-3A, EBNA-3B, and EBNA-3C and their functional domains. EBNA-3A, EBNA-3B, and EBNA-3C proteins are shown with the number of their amino acids and with a common domain that contains the RBP-J κ interaction domain. Also indicated are domains that have activating or repressive effects in addition to a variety of domains that associate with cellular proteins including CtBP, p300/HDAC1-2, pRB/cyclin A, prothymosin- α (Prot α), Skp2/Cul1/Roc1/c-Myc, Spi-1/Spi-B, SUMO, Nm23-H1, SMN, DP103/Gemin3, and p300. Nuclear localization signals (NLSs), a leucine zipper (BZIP), acidic domains, a proline (P)-rich region, and a glutamine (Q) and proline region are shown. (From Sims K, Saha A, Robertson ES. Regulation of cellular processes by the Epstein-Barr Virus nuclear antigen 3 family of proteins. In: Robertson ES, ed. *Epstein-Barr Virus: Latency and Transformation*. Philadelphia: Caister Academic Press, 2010:81–100, with permission.)

Although significantly divergent in nucleotide and amino acid sequence, type 1 and type 2 EBNA-3A, EBNA-3B, and EBNA-3C have similar effects in B-cell growth transformation.¹⁴⁶¹ EBV recombinants made in a type 2 EBV P3HR-1 background with type 1 EBNA-LP and EBNA-2 have the robust primary B-cell transformation phenotype characteristic of type 1 EBV strains. Replacement of the P3HR-1 type 2 EBNA-3s with type 1 EBNA-3s does not alter infected B-cell outgrowth to LCLs or the ability of the recombinant virus to replicate in response to induction of permissive infection. Thus, EBNA-3 type specificity does not affect latent or lytic virus infection of B lymphocytes *in vitro*.

EBNA-3B is not critical for latent infection of primary B cells, for LCL outgrowth, for cell survival, or for lytic virus replication.^{201,773,1462} Finding that EBNA-3B is not essential for any aspect of lymphocyte infection *in vitro* is surprising because EBNA-3B epitopes are frequently recognized by human immune cytotoxic T lymphocytes. Immune recognition would be expected to provide strong *in vivo* selection against a nonessential gene. Consistent with the lack of effect of the putative null EBNA-3B mutation on lymphocyte infection and LCL outgrowth *in vitro* and the expectation that EBV strains with altered or absent EBNA-3B genes would be expected to emerge under immune selection, an EBV mutant with a truncated EBNA-3B ORF was discovered in a transplant patient with EBV-associated lymphoproliferative disease who was undergoing therapy with anti-EBNA-3B cytotoxic T lymphocytes.⁴⁷⁹

In contrast to the lack of phenotype associated with truncation of the EBNA-3B ORF, nonsense codons after codon 302 of EBNA-3A or codon 365 of EBNA-3C result in EBV recombinants that are unable to transform primary B cells.^{741,1463} These experiments were the first to indicate that EBNA-3A and EBNA-3C are critical for B-cell growth transformation or survival and differ significantly from EBNA-3B in their roles in EBV infection. Interestingly, despite collinear homology, rhesus LCV EBNA-3A, EBNA-3B, and EBNA-3C cannot substitute for EBV EBNA3s in transformation of human B cells into LCLs, consistent with species-specific roles for EBNA-3A, EBNA-3B, or EBNA-3C in LCL outgrowth.⁶⁸⁶

Studies with conditional mutant forms of EBNA-3A or EBNA-3C confirm the importance of these proteins for LCL growth and have allowed extensive studies of domains of EBNA-3A or EBNA-3C required for LCL growth.^{985,986,988–990,1360} This genetic analysis used viral genomes in which the EBNA-3A or EBNA-3C terminus is fused in frame to a 4OH-tamoxifen (4HT)-dependent mutant estrogen receptor hormone binding domain.⁹⁸⁵ The resultant EBV EBNA-3AHT or EBNA-3CHT transformed LCLs conditionally express EBNA-3AHT and EBNA-3CHT. In 4HT, EBNA-3AHT or EBNA-3CHT LCLs grow similarly to wild-type LCLs. In the absence of 4HT, the LCLs slowly stop growing and gradually die. Addition of 4HT restores exponential cell growth.

Wild-type or mutant EBNA-3A or EBNA-3C complementation in LCLs transformed by the conditional EBV

EBNA-3AHT or EBNA-3CHT has identified regions within EBNA-3A and EBNA-3C that are not required for LCL growth.^{985,989} These studies have also identified domains of EBNA-3A and EBNA-3C that are required for continued LCL growth^{986,989,990,1360} (Fig. 61.9A). EBNA-3A and EBNA-3C mutants in the RBP-J κ binding site are deficient in repression of EBNA-2 activation of the EBV Cp enhancer and in LCL growth.^{986,989} Thus, EBNA-3A and EBNA-3C regulation of transcription through RBP-J κ /CBF1 is critical for LCL growth. More recent studies have been particularly illuminating in regard to EBNA-3A and EBNA-3C function. Initially, it was shown that EBNA-3C inactivation resulted in the accumulation of p16 (INK4A) and decreases in the hyperphosphorylated form of Rb, resulting in a smaller number of cells in S or G2/M phase.⁹⁸⁸ In more recent studies, it was demonstrated that epigenetic repression of p16 (INK4A) and p14 (ARF) expression mediated by EBNA-3A and EBNA-3C are required for LCL growth.^{990,1360} Moreover, human papillomavirus type 16 E7 and E6 expression was able to sustain LCL growth after inactivation of EBNA-3C or EBNA-3A.⁹⁹⁰ Interestingly, binding to the C-terminal-binding protein (CtBP) by both EBNA-3A and EBNA-3C is required for LCL growth.¹³⁶⁰ Thus, the interaction of EBNA-3A with CtBP is only now beginning to be understood⁵⁷⁷ as well as the significance of the finding that the cellular protein BIM is epigenetically regulated by EBNA-3A and EBNA-3C.^{36,1140}

Despite the absence of homology, EBNA-3A, EBNA-3B, and EBNA-3C are similar to EBNA-2 in stably associating with RBP-J κ .^{696,802,979,1228,1229,1512,1627} The EBNA-3 family can significantly alter cell gene transcription, and in many cases there is a remarkable similarity in this regulation consistent with coordinated effects on cell gene transcription.^{202,572,958,1384,1540,1626} In associating with RBP-J κ , the EBNA-3s compete for RBP-J κ with EBNA-2 and Notch and limit EBNA-2 up-regulation through RBP-J κ . An RBP-J κ domain as small as amino acids 125 to 181 can bind to EBNA-3C, and amino acids 172 to 223 of EBNA-3C, which are relatively well conserved in EBNA-3A and EBNA-3B, can interact with RBP-J κ (Fig. 61.9A).^{696,802,979,1228,1229,1512,1627} EBNA-3A amino acids 224 to 556 can also bind to RBP-J κ .²³⁹ EBNA-3A, EBNA-3B, and EBNA-3C bind more tightly to RBP-J κ than EBNA-2 and can displace EBNA-2 from RBP-J κ . Most of the RBP-J κ in LCLs is associated with EBNA-2, EBNA-3A, EBNA-3B, and EBNA-3C.⁶⁹⁶ Two- to threefold overexpression of EBNA-3A in LCLs is sufficient to dissociate RBP-J κ from the strong up-regulatory effects of EBNA-2, decrease c-myc expression, and stop LCL growth.²⁶¹

Other studies have also highlighted the importance of EBNA-3C in mediating gene transcription. EBNA-3C interaction with RBP-J κ is important for up-regulating TCL1.⁸⁵⁰ EBNA-3C has also been implicated in suppressing the ATM/Chk2-mediated DNA damage-responsive signaling pathway that is important in EBV transformation.^{235,1093}

Several lines of evidence indicate that EBNA-3C can have transcriptional up-regulatory effects alone or in concert with EBNA-2. When expressed alone in B-lymphoma cells, EBNA-3C can up-regulate CD21 expression and does not affect CD23, CD10, CD30, CD39, CD40, CD44, or cellular adhesion molecule expression.¹⁵¹⁸ Raji latency 3 BL cells do not express EBNA-3C as a consequence of a deletion in the Raji EBV genome. When Raji cells reach saturation, they undergo

growth arrest in G1 and LMP1 levels fall. EBNA-3C expression in Raji cells sustains LMP1 levels when the cells grow to saturation,²⁰ consistent with the notion that EBNA-LP co-activation of the LMP1 promoter with EBNA-2 ceases at saturation and is replaced by EBNA-3C co-activation. In support of this hypothesis, EBNA-3C is unique among EBNA-3s in co-activating the LMP1 promoter with EBNA-2.^{690,892,1629} The EBNA-3C leucine zipper interacts *in vitro* with the PU.1-Ets domain and appears to up-regulate transcription through the LMP1 promoter PU.1 binding site.¹⁶²⁹ The EBNA-3C effect is independent of the RBP-J κ binding site in the LMP1 promoter and of the RBP-J κ interaction domain in EBNA-3C.¹⁶²⁹ Furthermore, EBNA-3C fully co-activates with WW to SS mutant EBNA-2, which cannot interact with RBP-J κ .⁸⁹² EBNA-3C amino acids 365 to 545, which have repressive activity in the context of fusions to the Gal4 DNA binding domain,⁷⁰ are essential for co-activation with EBNA-2.^{892,1240} Point mutations of residues within that domain abrogate EBNA-3C co-activation with EBNA-2. SUMO1, 2, and 3 bind to this site in EBNA-3C. Point mutations that disrupt EBNA-3C co-activation also disrupt SUMO binding. Furthermore, overexpression of SUMO or UBC9 co-activates the LMP1 promoter with EBNA-2 in the absence of EBNA-3C.¹²⁴⁰ Moreover, EBNA-2-mediated promoter activation is dependent on p300, and EBNA-3C potentiation of p300 transcriptional effects is abrogated by the same point mutations. These data are consistent with a model in which SUMO association with EBNA-3C at the LMP1 promoter activates p300 and potentiates EBNA-2-enhanced transcription.^{892,1240} Other data identify EBNA-3C glutamine- and proline-rich amino acids 724 to 826 as activators of transcription from a GAL4-responsive promoter when fused to the GAL4 DNA binding domain.⁹⁷⁹ The EBNA-3C C-terminal domain can interact with Nm23-H1 in transcriptional activation¹⁴⁰¹ and modulate necdin activity.⁷²⁴ EBNA-3C can also recruit the p300 histone acetylase through an interaction with prothymosin α .^{265,1399,1400} EBNA-3B binds Spi-1/Spi-B, which is important for binding an EBNA-3C-responsive element in the LMP1 promoter.^{834,1629} EBNA-3C can directly bind to the tumor suppressor protein p53 and repress its functions, in part by blocking its transcriptional activity as well as facilitating its degradation through stabilization of its negative regulator, Mdm2.¹²⁶⁵ More recent studies have demonstrated that EBNA-3C can negatively regulate p53-mediated functions by interacting with the inhibitor of growth family proteins ING4 and ING5.¹²⁶³ Both ING4 and ING5 bind to N-terminal domain residues 129 to 200 of EBNA-3C,¹⁵⁹² which associates with p53 and is also essential for LCL growth. EBNA-3A activity as well as Mdm2-dependent mechanisms may be important in preventing apoptosis of LCLs in which the p53 pathway is active.⁴¹¹ EBNA-3C has repressive effects on the EBV Cp promoter, which is dependent on RBP-J κ sites in the promoter plasmid and partially on HDAC1 binding.^{1201,1202} Full-length EBNA-3C fused to the GAL4 DNA binding domain also represses transcription and EBNA-3C amino acids 280 to 525 and 580 to 992 have repressive effects in the context of Gal4 fusions.^{70,125}

EBNA-3C has been reported to cooperate with Ras in transforming rat embryo fibroblasts and to interact at a low level with Rb in activation of an E2F site in the B-myc promoter.^{1137,1138} In NIH3T3 fibroblasts or human U2OS cells compelled to arrest by serum withdrawal, EBNA-3C

expression can inhibit p27 (K1P1) accumulation and cause bi- or multinucleated cells by abrogating the mitotic spindle checkpoint.¹¹³⁸ Because bi- or multinucleated cells are not a characteristic of EBNA-3C expression levels in latency 3 EBV-infected B cells, the relevance of these observations is uncertain. EBNA-3C has also been shown to interact with and modulate cyclin activity including the cyclins A, D1, and E. This modulation may effect progression through the cell cycle in EBV-transformed cells.^{787,788,1264} EBNA-3C recruits the ubiquitin ligase Skp1/Cul1/F-box complex, resulting in ubiquitination of the cell cycle regulators Rb and p27.^{789,790} Recently, it was shown that EBNA-3C stabilizes Gemin3 to block p53-mediated apoptosis.¹⁵⁰

EBNA-3A also represses Cp promoter activity in B cells and in epithelial cells, and this activity is largely dependent on the domain through which EBNA-3A interacts with RBP- κ .²³⁹ Using GAL4 EBNA-3A fusion proteins and GAL4-responsive promoters, the EBNA-3A-repressive domain has been mapped to 143 amino acids that do not interact with RBP- κ and can mediate down-regulation of transcription.^{125,986} EBNA-3A also has a weak, B-cell-biased, activation domain that is evident when EBNA-3A deleted for the amino acids 100 to 364 repressive domain is fused to the GAL4 DNA binding domain and expressed in B lymphoblasts along with a GAL4-responsive promoter.²³⁹ An EBNA-3A bait in a yeast two-hybrid search for interacting proteins retrieved the carboxyl part of the epsilon subunit of the chaperonin T-complex protein 1 and the p38 subunit of the aryl hydrocarbon receptor complex.^{717,718} EBNA-3A associates with the p38 subunit and partially relocates it to the nucleus.

Single gene transfer of EBNA-3B into DG75 BL cells results in up-regulation of vimentin, CD40, and Bcl-2 expression and down-regulation of CD77, compatible with these being EBNA-3B-regulated genes.^{1343,1344} A more comprehensive analysis identified 550 genes regulated by EBNA-3C. As expected, EBNA-3C-regulated genes overlapped significantly with genes regulated by EBNA-2 and EBNA-3A, consistent with coordinated effects on cell gene transcription.¹⁶²⁶

LMP1

LMP1 is a constitutively active tumor necrosis factor (TNF) receptor mimic (Fig. 61.10),^{667,669,670,1060} essential for primary B-lymphocyte conversion to LCLs.^{314,315,730-732,762} LMP1 supports LCL survival and growth by inducing cell activation pathways, such as mitogen-activated protein kinase (MAPK), JNK, phosphatidylinositol 3-kinase (PI3K)/Akt, nuclear factor- κ B (NF- κ B), and interferon response factor 7 (IRF7).^{348,351,354,522,761,960,1035,1095,1373,1623} Depending on cell type, LMP1 is transcribed from two different promoters separated by about 600 bp. In B cells, LMP1 is encoded by a 2.8-kb mRNA, which initiates from a site (ED-L1 promoter) that is dependent on EBNA-2.⁶⁹⁴ ED-L1 can also be activated independently of EBNA-2 by cellular factors, such as STATs, IRF7, and activating transcription factor 4 (ATF4).^{206,844,1096,1359} The p38 signaling pathway up-regulates LMP1 expression.⁶⁹⁷ Enhancement of LMP1 expression up to 200-fold can be mediated by the EBNA-1-dependent transcriptional enhancer FR in *oriP* acting across the fused TRs.⁴⁴² In epithelial cells, LMP1 transcription is mediated by an upstream promoter (L1-TR) that initiates transcription from multiple TATA-less sites in the nearest copy of TR resulting in a

3.5-kb transcript with a long untranslated 5' exon^{461,1262} and is in part dependent on the cellular factors Sp1 and STAT3.^{461,1262} Interestingly, LMP1 expression was observed to be greater with fewer TRs¹²¹⁷ and LMP2A can negatively regulate the expression of LMP1 from this promoter.¹³⁹³ The LMP1 ORF has two short introns.^{74,388} While EBNA proteins are remarkably stable, LMP1 has a short half-life. Nevertheless, LMP1 accumulates at high levels and localizes to a large plasma membrane patch in LCLs.^{563,888,890} LMP1 can have opposing effects on cell growth, enhancing proliferation at physiologic doses but being cytostatic at high levels.^{275,406,525,733} This in part is likely related to the observation that LMP1 can induce autophagy.⁸⁴³

In LCLs, LMP1 constitutively forms discrete patches or a large cap in the plasma membrane.⁵⁶³ LMP1 has six transmembrane domains (Fig. 61.10). Live cell protease cleavage studies of LCLs indicate that the LMP1 N- and C-termini are on the cytoplasmic side of the plasma membrane. Only three short reverse turn domains are on the extracellular side of the plasma membrane, and almost half of LMP1 is in the plasma membranes.⁸⁹⁰ In epithelial cells or fibroblasts, LMP1 is more broadly distributed in surface and internal cytoplasmic membrane patches.¹⁵¹⁵⁻¹⁵¹⁷ LMP1 aggregation is an intrinsic effect of the multiple hydrophobic transmembrane domain and does not change in the absence of exogenous growth factors.^{888,890} Extraction of cells with nonionic detergents reveals more than half of LMP1 to be associated with the cell cytoskeleton.^{67,888,969,1049,1051} Although vimentin is not ordinarily found in a plasma membrane patch, vimentin co-localizes with LMP1 in latently infected B-cell plasma membranes and is required for LMP1 association with the lymphocyte cytoskeleton.^{887,888} Vimentin can also further direct LMP1's localization. When vimentin relocates into perinuclear rings and coils in response to Colcemid, LMP1 relocates to vimentin rings. However, LMP1 also forms patches and caps in plasma membranes of cells that lack vimentin and does not require vimentin for signal transduction.⁸⁸⁷ The association of LMP1 with plasma membranes is at least in part mediated by cholesterol-rich membrane microdomains termed *lipid rafts*.^{45,46,581}

LMP1 is phosphorylated on serine and threonine residues at a ratio of 6:1 and is not tyrosine phosphorylated.^{888,969,1049,1051} The half-life of LMP1 in LCLs as measured by time to reach stable levels of ³⁵S-methionine in LMP1 and by pulse chase is 3 to 5 hours.^{67,888,969} Nonionic detergent-soluble LMP1 has a half-life of much less than 5 hours and is converted to more stable cytoskeletal-associated and phosphorylated LMP1.^{888,969,1049,1051} LMP1 is also cleaved near the beginning of the C-terminal cytoplasmic domain, resulting in a transiently stable soluble 25-kD C-terminal cytoplasmic domain.^{1049,1051} The principal phosphorylation sites are in the 25-kD cleavage product.¹⁰⁵⁰

In single gene transfer experiments using heterologous promoters, LMP1 has transforming or "oncogene" effects in continuous rodent fibroblast cell lines.¹⁵¹⁵ LMP1 alters Rat-1 or NIH 3T3 cell morphology, enables growth in medium supplemented with low serum, causes loss of contact inhibition, and enhances growth as tumors in nude mice. Rat-1 or Balb/c 3T3 cells also lose anchorage dependence and grow in soft agar after LMP1 expression.^{1515,1516} The growth of Balb/c 3T3 cells in soft agar correlates quantitatively with the extent

FIGURE 61.10. Schematic diagram of biochemical mechanisms by which latent membrane protein 1 (LMP1) affects cell growth and survival pathways by constitutively mimicking the activated tumor necrosis factor (TNF) receptor CD40. The six hydrophobic transmembrane domains of LMP1 enable it to aggregate in lipid rafts within the plasma membrane. The amino terminal cytoplasmic domain is fully dispensable for primary B-lymphocyte growth transformation and its primary function is in tethering the amino terminus of the first transmembrane domain to the cytoplasmic side of the plasma membrane. The transmembrane domains and the C-terminal cytoplasmic domain are essential for primary B-lymphocyte growth transformation. The C-terminal cytoplasmic domain is 200 amino acids and has two essential components (CTAR1/TES1 and CTAR2/TES2). CTAR1/TES1 follows the transmembrane domains and the first 44 amino acids associate with TNF receptor-associated factors (TRAFs), which activate noncanonical nuclear factor- κ B (NF- κ B) signaling through NF- κ B-inducing kinase (NIK) and inhibitor of κ B kinase α (IKK α). The second, CTAR2/TES2, is at the C-terminus of LMP1 and associates with the TNFR-associated death domain proteins including TNFR1-associated death domain (TRADD) and receptor-interacting protein (RIP) without propagating a death signal. BS69 and IRF7 also bind to CTAR2/TES2. Canonical NF- κ B signaling through IKK β is mediated through a TAB1/TAK1-dependent mechanism. TRAF activation involves UBC13-dependent Lys 63-linked polyubiquitination. The JNK/AP1 pathway is TRADD independent. The linker region between CTAR1/TES1 and CTAR2/TES2 can be deleted without loss of B-lymphocyte-transforming activity.

of LMP1 expression up to the levels ordinarily expressed in LCLs.^{69,1051,1516} LMP1 mutants that have transforming activity when expressed at levels similar to LCLs can be toxic when expressed at higher levels.⁹⁸³ Comparison of the transforming properties of LMP1 with those of D1LMP1, which has only transmembrane domains 4 and 5 and the C-terminus and is expressed in lytic infection, indicates that D1LMP1 lacks these effects^{68,1050,1516} and can inhibit the transforming function of LMP1.¹¹³⁰ Because D1LMP1 lacks the N-terminal cytoplasmic domain and the first four transmembrane domains, inserts into cell membranes, and does not

patch, these data indicate that the amino terminus and the first four transmembrane domains are essential for LMP1 aggregation in membranes and transforming effects in rodent cells. Addition of the 25-amino acid N-terminal cytoplasmic domain to the amino terminus of D1LMP does not restore the ability to cause anchorage-independent growth of Balb/c 3T3 cells.^{68,1050} C-terminal cytoplasmic domain truncations have variable effects but are consistently unable to cause loss of contact inhibition in Rat-1 cells.¹⁰⁵⁰ These data suggest that the C-terminal cytoplasmic domain is important for loss of contact inhibition in Rat-1 cells.

LMP1 dramatically alters the growth of EBV-negative BL lymphoblasts, primary B lymphocytes, or epithelial cells when expressed stably or transiently at the appropriate level following gene transfer.^{110,887,1151,1152,1155,1248,1517,1518} LMP1 induces many of the changes usually associated with EBV infection of primary B cells or with antigen activation of primary B cells, including cell clumping; increased villous projections; increased vimentin expression; increased cell surface expression of CD23, CD39, CD40, CD44, and class II major histocompatibility complex (MHC); increased IL-10 expression; decreased expression of CD10; and increased expression of the cell adhesion molecules leukocyte function-associated antigen-1 (LFA-1), intracellular adhesion molecule-1 (ICAM-1), and LFA-3.¹⁵¹⁷ LMP1 not only increases plasma membrane expression of adhesion molecules but also activates adhesion and induces higher levels of LFA-1 mRNA. LMP1 effects on cell adhesion are important because homotypic B-cell adhesion or adhesion to other cells can facilitate autocrine or paracrine growth factor effects. D1LMP1 has none of these effects, confirming the importance of the amino terminus and multiple transmembrane domains. LMP1 also protects B lymphocytes from apoptosis, in part through induction of bcl-2 expression.^{490,558,1248} Despite the robust and pleiotropic effects of LMP1 expression in human B-lymphoma cells, the effects of deletion mutants that partially affect the membrane patching properties of LMP1 on each of the phenotypes is intermediate, without a clear loss of some effects and the retention of others.⁸⁸⁹ LMP1 expression also alters cell growth and gene expression in a variety of cell types with resulting phenotypes and changes in cell gene expression compatible with the broad effects LMP1 has on cell survival, gene expression, and signaling.^{234,289,291,292,337,369–371,427,558,623,798,812,813,913,1500,1604,1605}

LMP1 also affects epithelial and B-lymphocyte cell growth, survival, and differentiation in transgenic mouse models. LMP1 expression in the skin and esophagus of three lineages of mice under control of the polyomavirus enhancer and promoter results in induction of the expression of a hyperproliferative keratin, K6; epidermal hyperplasia; and thickening of both parabasal and keratinizing layers.¹⁵⁴⁵ Further, LMP1 expression under the control of the immunoglobulin heavy chain promoter and enhancer in three lineages of transgenic C57/bl6 mice backcrossed into Balb/c mice results in markedly increased B-cell hyperplasia and lymphomas.⁸¹¹ Massive spleen enlargement and lymphoma increases significantly with age. Lymphomas are unusual before 12 months and develop in 42% of transgenic mice over 18 months of age. The lymphomas are monoclonal or oligoclonal by immunoglobulin H (IgH) rearrangement and frequently invade and metastasize, and LMP1 is expressed at LCL levels. These data indicate that LMP1 can be oncogenic in B cells *in vivo*. B cells of transgenic mice expressing LMP1 under the control of the immunoglobulin promoter and enhancer also have enhanced expression of activation antigens, spontaneously proliferate, and produce antibody.¹⁴⁸¹ In CD40-deficient or normal backgrounds, LMP1 expression mimics CD40 signals and induces extrafollicular B-cell differentiation, blocking germinal center formation. Transgenic mice expressing LMP1 under the control of an immunoglobulin heavy chain promoter and enhancer develop lymphoma at a threefold higher incidence than LMP1-negative mice. LMP1 immunoprecipitates with TNF receptor-associated factors (TRAFs) 1, 2, and 3, and NF- κ B, c-Rel, Akt, JNK, STAT, and p38 are activated in LMP1-associated lymphomas.^{1325,1447}

Illustrative of the similar pathways that LMP1 and CD40 activate, mice expressing a constitutively active CD40 receptor, in the form of an LMP1/CD40 chimeric protein, have B cells with an activated phenotype, prolonged survival, and increased proliferation, which results in B-cell lymphomas.^{601,1208} EBV conversion of primary B cells to LCLs is stringently dependent on LMP1 expression and therefore is a suitable system to identify the important LMP1 components.^{730,732} The LMP1 first transmembrane domain (TM1) and cytoplasmic C-terminus (CT) are essential for LCL outgrowth.^{730,732} LMP1 deleted for the N-terminal cytoplasmic domain and part of TM1 is a stable protein, which localizes to the plasma membrane and does not aggregate or enable LCL outgrowth.^{730,889} Similarly, LMP containing only TM3-6 and the CT is a null mutation, which localizes to all cytoplasmic membranes and does not accumulate or aggregate in the plasma membrane or enable LCL outgrowth. These mutant effects are unlikely to be due to specific interactions mediated by the N-terminal cytoplasmic domain, because deletion of any part of the N-terminal cytoplasmic domain results in at least 10% residual transforming efficiency and the resulting LCLs grow normally.⁶⁶⁸ Further, at least part of the CT is critical because expression of the N-terminus and TM1-6 without the 200-amino acid CT is null for LCL outgrowth.⁷³² Moreover, an EBV recombinant that expresses the LMP1 N-terminus, TM1-6, and CT first 44 amino acids is dependent on fibroblast feeder layers or cross-feeding from multiple transforming events for LCL outgrowth, whereas an EBV recombinant that expresses the LMP1 N-terminus and TM1-6 and is deleted for only the CT first 24 amino acids does not result in LCLs.⁶⁶⁹ These data indicate that the CT first 24 amino acids are essential for LCL outgrowth and that efficient LCL outgrowth also requires the CT last 155 amino acids.^{315,669} Surprisingly, within the CT last 155 amino acids, mutation of the most C-terminal YYD to ID identifies this site as critical for LCL outgrowth, whereas deletion of amino acids 232 to 351 has no effect on LCL outgrowth, LCL growth characteristics, or lytic EBV replication.^{666,670} Thus, the non-transforming phenotype with a deletion of the N-terminus and TM1 or a deletion of the CT first 24 amino acids, and the near-null transforming effect of mutation of the CT last three amino acids from YYD to ID, identify TM1 and the CT first 24 and last 3 amino acids as critical for LCL outgrowth, whereas amino acids 232 to 351 are not important. The two critical C-terminal transformation sites are therefore referred to as CT transformation effector sites 1 and 2, or TES1 and TES2.

In parallel with the initial genetic analyses of the role of the LMP1 CT first 44 amino acids in LCL outgrowth,⁷³² investigations of the biochemical basis of LMP1 effects in up-regulating B-cell activation markers, adhesion molecules, the HIV promoter, and A20 expression identified LMP1 to activate NF- κ B.^{522,822} Based on the role of the LMP1 CT first 44 amino acids in enabling transformation, yeast two-hybrid, biochemical pull-down, and in-cell-association experiments were undertaken, which identified TES1 interactions with a human protein TRAF3,¹⁰⁶⁰ which is related to mouse TNF receptor II (TNFRII) factors.¹²⁴² A related human protein, TRAF1 also associated with LMP1.¹⁰⁶⁰ This was of interest because CD40 is the principal pro-survival TNFR for B cells and is similar to the LMP1 CT TES1 amino acid sequence. CD40 engages TRAF3 and has effects in B cells that are similar to LMP1.^{73,306,729,1060}

This allowed the realization that LMP1 is a constitutively activated TNFR. In support of this model, TES1 correlated with a principal LMP1 CT NF- κ B activation domain, C-terminal activating region (CTAR) 1, and TES2 correlated with a second LMP1 NF- κ B activation domain, CTAR2.^{633,1035} The LMP1 CT/TES2/CTAR2 terminal 11 amino acids interact with and associate with TNFR1-associated death domain (TRADD) and receptor interacting protein (RIP) death domains but do not initiate a death signal.^{667,670,671} LMP1 also associates with a number of other cellular proteins including A20 and Ubc9.^{97,428} A20 regulates LMP1 activation of IRF7.¹⁰⁹⁷ The interaction with Ubc9 was localized to a region between CTAR1/TES1 and CTAR2/TES2 (see later) termed CTAR3. This region was previously reported to bind and activate DNA binding of STAT1⁴⁶⁴; however, more recent studies indicate that JAK3 only weakly associates with both LMP1 and LMP1 lacking the putative JAK3 binding domain.⁵⁸² More importantly, this region was shown not to induce STAT1 transcriptional activity or be important for the functions of LMP1 described later. Although essential for LMP1 signaling, the LMP1 TMs can be replaced by CD2-CTAR1 or CD2-CTAR2 expression, using anti-CD2 antibody to induce aggregation.^{405,465} The two LMP1 CT activation and transformation domains activate NF- κ B, JNK, p38, IRF and cdc42 pathways.^{133,305,350–354,404,405,420,541,760–762,1026–1029,1191,1280,1415,1481,1589,1590}

Within the LMP1 CTAR1/TES1 region is a PXQXTDD motif that approximates CD40 interactions with a shallow canyon on the TRAF3 surface, stabilizing trimer formation.^{1563,1589} Extensive studies have shown that LMP1 utilizes TRAFs and proteins essential for the NF- κ B and IRF7 pathway to signal.^{44,117,133,305,306,353,404,482,541,569,643,805,961,1027,1060,1095,1266,1280,1373,1482,1563,1569–1571} Through the interactions with TRAF1-3 and TRAF5-6 LMP1 CTAR1/TES1 activates both the non-canonical pathway and the canonical NF- κ B pathways by stabilizing NF- κ B-inducing kinase (NIK), which phosphorylates inhibitor of κ B kinase α (IKK α)-activating NF- κ B.^{53,349,353,1029,1127,1266,1415} TRADD, RIP, and IRF7 binding within CTAR2/TES2 appears to primarily activate TRAF6 and IKK β .^{53,939–941,1306,1310,1373} BS69, a cellular MYND domain-containing protein, also binds CTAR2/TES2, and knock-down of BS69 interferes with JNK activation.^{1513,1514} LMP1 also induces Lys 63-linked polyubiquitination of TRAF6, which is likely mediated by UBC13.^{939,1374} A unique aspect of LMP1-mediated canonical signaling is incomplete dependence on IKK γ .⁹⁴⁰ Furthermore, interleukin- α receptor-associated kinase 1 (IRAK1) is required for LMP1 noncanonical and canonical signaling, due to a surprisingly central role for IRAK1 in p65 S536 phosphorylation.¹³⁷⁴

LMP1 provides both growth and survival signals for LCL growth. In an LCL with conditional LMP1 expression, cells exit the cell cycle in the absence of LMP1 and survive for 5 days.⁷⁶² LMP1 protects BL cells from the pro-apoptotic effects of growth factor withdrawal^{558,1248} and is the principal activator of NF- κ B in LCLs.^{146–149} NF- κ B inactivation results in rapid apoptosis, which proceeds despite high bcl-2 and bcl-XL levels. Mitochondrial membrane potential decreases rapidly, cytochrome C is not released, and bax is activated. Caspases are also activated. Caspase inhibitors can prevent activation but not apoptosis. Bfl-1, c-Flip, A20, and c-IAP mRNAs decrease rapidly, implicating these proteins as candidate triggers of cell death.

Because LMP1 activation of NF- κ B is critical for cell survival and is dependent on effective LMP1 aggregation, the basis for TM aggregation has been investigated. Surprisingly, LMP1 containing TM1-2 and CT can induce 30% to 40% of wild-type LMP1 CT signaling, whereas LMP1 with TM3-4 and CT or TM5-6 and CT lack activity.^{243,1585} Further, LMP1 with TM1-4 and CT has 70% to 80% of wild-type signaling.¹⁵⁸⁵ A point mutation analysis of the role of TM1-2 specific amino acids in effective aggregation identified FWLY41 at the external surface of TM1 as critical for LMP1 signaling.¹³⁷⁵ LMP1 with FWLY mutated to AALA is markedly deficient in raft association and has less than 20% of wild-type LMP1 NF- κ B activation. TM1-2 with the AALA mutation is also very deficient in intermolecular association with TM3-6 expressed as another protein. These data are consistent with a model in which TM1 FWLY is critical for raft association and intermolecular interactions necessary for signaling.

LMP2A and LMP2B

LMP2A constitutively mimics signaling from the B-cell receptor (BCR) (Fig. 61.11). As a result, EBV latent membrane proteins mimic two signals that are essential for normal B-cell development and function: LMP1 mimics a CD40 signal, while LMP2A mimics a BCR signal. LMP2B is related to LMP2A but lacks the domain required for LMP2A tyrosine kinase signaling (Fig. 61.11). LMP2A and LMP2B in latency 3 are expressed from unique EBNA-2-responsive promoters that have RBP-J κ and PU.1 sites, which LMP2A has and LMP2B shares with the LMP1 promoter.^{834–836,838,1008,1277,1636} In latency 2, in which EBNA-2 is not expressed and LMP1 and LMP2A are expressed, LMP2A has been shown to autoactivate its expression through Notch, providing a mechanism for expression independent of EBNA-2.³³ Interestingly, LMP1 is not as consistently expressed in latency 2 as LMP1.^{136,576} A recent study has shown that LMP2A in epithelial cells can block LMP1 expression by LMP2A, inhibiting IL-6 secretion and preventing autocrine secretion and activation of the L1-TR LMP1 promoter by STAT3 activation.¹³⁹³ The LMP2A first exon encodes 119 N-terminal cytosolic amino acids that precede a methionine, which is the translational start site for the LMP2B mRNA. LMP2A and 2B mRNAs share remaining exons, which encode 12 membrane-spanning domains separated by short reverse turns and a 27-amino acid C-terminal cytosolic domain.^{836,1277} (Fig. 61.11). LMP2B consists primarily of 12 membrane-spanning domains and lacks the LMP2A N-terminal domain. Recently, using RNA-seq, alternative LMP2 splicing events have been identified.²⁵⁸ Several studies have suggested that LMP2B can augment LMP1 signaling and negatively regulate the function of LMP2A.^{1212,1213,1245} No antibody reagents specific to LMP2B have been developed to date, and as a result, expression patterns for LMP2A are what have been most characterized. Similar to LMP1, LMP2A localizes to patches in membranes of latently infected B lymphocytes, where it co-localizes with LMP1.^{920,921} A related LMP2A transcript has been identified in NK- and T-cell lymphoproliferative disease that initiates from within the EBV terminal repeats and containing downstream, epitope-encoding exons that may encode targets for cellular immunotherapy.⁴¹⁴

LMP2A is palmitoylated, although the function is uncertain.^{581,723,993} LMP2A also associates with lipid rafts, which

FIGURE 61.11. Schematic diagram of biochemical mechanisms by which latent membrane protein 2 (LMP2) activates signaling pathways by constitutively mimicking an activated B-cell receptor. LMP2A is constitutively localized to lipid rafts and binds Src family tyrosine kinase such as Lyn, leading to constitutive phosphorylation of LMP2A at multiple tyrosine residues. Syk is recruited by the phosphorylated intracellular adhesion molecule (ITAM), where it becomes activated. LMP2A also binds E3 ubiquitin ligases in the Nedd4 family and may also bind mitogen-activated protein kinase (MAPK). LMP2A blocks the ability of the B-cell receptor (BCR) to enter lipid rafts. Phosphatidylinositol 3-kinase (PI3K) is constitutively phosphorylated in cells expressing LMP2A, as is SLP-65 and Btk. The antiapoptotic serine/threonine kinase Akt is constitutively phosphorylated in cells expressing LMP2A, representing one possible way in which LMP2A inhibits apoptosis. MAPK and Ca^{2+} -dependent signal transduction may result from activation of PI3K, SLP-65, and Btk. E3 ubiquitin ligases mediate the degradation of LMP2A and associated factors, including Lyn. LMP2A can block BCR signal transduction in certain B-cell lines; however, it is unclear whether this is solely due to denying entry of BCR into rafts, sequestration of Syk and Lyn, desensitization of cells, or a combination of these effects.

is likely important for initial contact with src family tyrosine kinases.^{338,581} LMP2A lacking TM3-12 and the C-terminal cytoplasmic domain is diffusely localized in the plasma membrane.⁹²⁰ Indeed, the C-terminal cytoplasmic domain can have a direct role in self-association,^{993,1460} although LMP2A deleted for TM 6–12 and the C-terminal cytosolic domain can still partially block BCR signaling.¹⁰¹⁹ Even with deletion of TM3-12, the LMP2A C-terminus is still tyrosine phosphorylated.⁹²⁰

LMP2A is a substrate for, is associated with, and is constitutively phosphorylated by B-lymphocyte src family tyrosine kinases, especially Lyn.^{143,1017,1246} Lyn is likely recruited to LMP2A by the amino acids DQSL in LMP2A, which are similar to the amino acids DCSM in Ig- α .¹¹⁷² Lyn likely binds to Y112 of LMP2A through its SH2 domain and phosphorylates all LMP2A tyrosines (Y), resulting in recruitment of Syk to Y74 and Y85 and activation of PI3K, Btk, BLNK, Akt, and mTor.^{360,1011,1012,1017,1042,1413} LMP2A Y23, Y31, Y60, Y64, and Y101 phosphorylations are unnecessary for blocking BCR signaling.¹⁴¹³ LMP2A causes constitutive phosphorylation of PI3K and CrkL in B cells.^{360,1017} Antiphosphotyrosine antibodies localize LMP2A sites of constitutive tyrosine phosphorylation in the infected cell plasma membrane.⁹²⁰ LMP2A is one of the few stably tyrosine-phosphorylated proteins in BL cells or LCLs and as a result recruits cellular proteins that contain SH2 domains like Shb.⁹⁹⁴ LMP2A may also undergo serine/threonine phosphorylation. LMP2A S15 and S102 bind MAPK *in vitro* and are substrates for MAPK phosphorylation.^{920,1131}

The LMP2A N-terminus has two PPPPY motifs, which bind WW domains of Nedd4 family ubiquitin ligases, such as AIP4/Itchy, WWP2, Nedd4, or Nedd4-2.^{645,647–649,1546} This interaction causes the ubiquitination and degradation of LMP2A and associated proteins.⁶⁵¹

LMP2A and 2B have been extensively mutated in EBV recombinants.^{764,922–925,1234,1380} Except for one anomalous result,¹³¹ the specifically mutated recombinants transform primary B lymphocytes with wild-type efficiency. The resultant LCLs grow the same as wild-type EBV-transformed LCLs under standard culture conditions, in reduced serum, in soft agarose, and in SCID mice. Virus replication is also similar following treatment of latently infected lymphocytes with chemical inducers of lytic infection.^{764,922–925} LMP2A is required for outgrowth of LCLs that lack expression of a functional BCR.^{964,965}

LMP2A expression in BL lymphoblasts constitutively blocks the signal transduction events that would follow the cross-linking of surface IgM (sIgM), CD19, or class II MHC on cells that do not express LMP2A.^{1018,1019} This blockade is similar to the desensitization that occurs after sIg signal transduction.^{139,162} LMP2A mutants that are deficient in association with Lyn and Syk do not block signal transduction.^{430–432} LMP2A may deplete the cell of Lyn and Syk by the ubiquitin ligases, induce desensitization, or deplete lipid rafts of Lyn, thereby depriving the BCR of Lyn.³³⁸ Consistent with a desensitization mechanism, the basal tyrosine phosphorylation of many cell proteins, including Lyn, Syk, and the p85 subunit of

PI3K, are higher in LCLs transformed by EBV recombinants that express wild-type LMP2A versus EBV recombinants that do not express LMP2A. Furthermore, cross-linking of sIg on wild-type EBV-transformed LCLs results in abrogation of tyrosine kinase signaling at the first steps of src family and syk phosphorylation, whereas cross-linking of sIg on LMP2A null mutant recombinant-transformed LCLs results in normal sIg protein tyrosine kinase signal transduction, including transient phosphorylation of Lyn, Fyn, Syk, p85, Vav, PLC- γ , SHC, and Grb2.¹⁰¹⁷ Consistent with the desensitization model, CD8 fusion to the LMP2A N-terminus and cross-linking of CD8 result in an increase in intracellular Ca^{2+} and then refractoriness.⁸⁴

Cross-linking of sIg on primary B lymphocytes transformed by LMP2 null mutant recombinants results in normal sIg-mediated signal transduction and activation of EBV replication.¹⁰¹⁸ Further, the LMP2A block of lytic replication can be bypassed by activating protein kinase C and raising intracellular free calcium with phorbol ester and calcium ionophore treatment. Indicative of the ability of LMP2A to activate cellular pathways, expression of LMP2A can in some cases activate lytic replication.¹²⁹²

A second role for LMP2A may be to provide survival and differentiation signals to B cells. LMP2A expression in transgenic mice under control of the IgH chain promoter and enhancer enables sIg-negative B cells to escape from the bone marrow and colonize peripheral lymphoid organs, bypassing normal B-cell developmental checkpoints by constitutive activation of the Erk/MAPK pathway.^{34,155,156} Thus, LMP2A can mediate sufficient constitutive forward signaling to affect normal B-cell survival. The LMP2A effect is also evident in RAG 1(-/-) mice; requires Syk, Btk, and BLNK; and is dependent on the LMP2A immunoreceptor tyrosine-based activation motif (ITAM).^{360,1011,1012} Thus, LMP2A expression could have a role in latency type 2-infected lymphocytes in enhancing B-cell survival through activation of PI3K, Akt, and Ras.^{435,1183} Interestingly, in transgenic mice high-level LMP2A expression results in B-1 cells in bone marrow, spleen, and periphery, whereas low-level expression results in spontaneous germinal centers.^{179,646} Also, the level of LMP2 expression is partially regulated by N-terminal monoubiquitination.^{645,648} In murine models of Burkitt lymphoma, LMP2A has been shown to dramatically accelerate disease, and this is in part due to bypassing the requirement of mutation of the p53 pathway.^{106,142} Remarkably, tumors derived from LMP2A/Myc mice share a similar pattern of gene expression with Myc tumors derived from transgenic mice despite the absence of p53 pathway mutations in the LMP2A/Myc mice.¹⁰⁷

LMP2A is also expressed in type 2 latency in Hodgkin lymphoma and nasopharyngeal carcinoma. Constitutive forward signaling from LMP2 could also be important in the pathogenesis of these malignancies. LMP2A expression during B-cell development in mice results in decreased expression of E2A, EBF, and Pax-5, which are important for normal B-cell development^{1180–1183} and furthermore activates Notch, which may alter B-cell identity.³⁵ Transgenic LMP2A expression in normal mouse epithelium under control of the keratin 14 promoter resulted in no apparent effect.⁹¹⁹ LMP2A expression in epithelial cell lines results in hyperproliferation in raft cultures, alterations in differentiation, increased cloning efficiency in soft agar, and promotes epithelial cell spreading

and migration.^{21,413,436,799,935,1307–1309} AKT activation increases β -catenin and cell growth through the LMP2A ITAM and PY motifs.^{1055–1057,1147} LMP2A can also increase LMP1 signaling and inhibit TGF- β -associated apoptosis.^{290,437} LMP2A has also been shown to activate the human endogenous retrovirus HERV-K18 in infected B cells, which encodes a superantigen that strongly stimulates T cells.^{618,619}

In summary, LMP2A, like LMP1, delivers a potent cell survival signal to B lymphocytes and may provide a therapeutic target in EBV-associated cancers.

EBERs

The EBER RNAs are by far the most abundant EBV RNAs in latently infected cells. Estimates place the EBERs at 10^7 copies per cell.^{49,615,617} EBER1 is about 10-fold more abundant than EBER2 and is transcribed by RNA polymerase II and III, whereas EBER2 is solely transcribed by RNA polymerase III.^{615,616} The EBERs localize to the cell nucleus where they are complexed with the cellular proteins La and L22 proteins.^{409,859,1455–1457} EBER RNAs have stable secondary structures that persist in RNA La protein complexes.⁴⁷² La protein associates with the 3' terminus of the EBER RNAs,⁴⁷² while L22 associates with three sites in EBER1.^{316,410,1457} Upward of 50% of the cellular pool of L22 is found in complex with EBER1, and most EBER1 is precipitable with antibody to L22.¹⁴⁵⁵ Recent studies have shown that the EBERs can be secreted from cells in complex with La resulting in Toll-like receptor 3 (TLR3) signaling.⁶⁶³ Confocal microscopy has detected a small fraction of EBERs in the cytoplasm of interphase cells, although EBERs are tightly associated with chromosomes in metaphase cells, consistent with nuclear entry after mitosis.¹³¹² Although L22 shuttles from the nucleus to the cytoplasm, EBERs remain in the nucleus.⁴⁰⁹ Furthermore, a substantial fraction of L22 relocates from nucleoli to the nucleoplasm in the presence of EBER1.¹⁴⁵⁵ EBERs are not expressed in lytic infection.⁴⁶⁰

EBER expression in uninfected Akata cells partially duplicates the effect of EBV reinfection of Akata cells in restoring growth in soft agar, tumorigenicity in SCID mice, resistance to apoptosis, resistance to interferon- α (IFN- α)-induced apoptosis, and induction of bcl-2 or IL-10.^{796,797,987,1076,1251–1254,1335} Also, EBV latency 2 infection or EBER expression in MT-2 T cells results in a shorter cell doubling time, higher saturation density, and IL-9 secretion.^{1579,1603} In addition, EBV reinfection or EBER expression in gastric carcinoma cell lines increases insulin-like growth factor 1 (IGF1) expression.⁶⁶² The effects of EBER expression can be opposed by concomitant L22 expression.³⁴⁷ Studies have suggested that the interaction of the EBERs with L22 is functionally significant because Burkitt lymphoma cells expressing mutant forms of EBER1 are incapable of binding to and relocating L22 to the nucleoplasm from the nucleoli and have reduced capacity to enhance cell growth of Burkitt lymphoma cells compared to Burkitt lymphoma cells expressing wild-type EBERs.⁶¹⁴

EBERs are similar to adenovirus VA1 RNA, which blocks interferon-induced PKR phosphorylation and inhibition of translational initiation factor eIF-2 α .⁷⁸² EBER1 and EBER2 can partially substitute for VA1 in adenovirus replication¹⁰² and can inhibit PKR *in vitro* at levels that are similar to VA1 RNA.^{238,1076,1330} In contrast, PKR activation *in vivo* is unaffected by EBER expression.^{1251,1533} This may reflect the distinct

subcellular compartmentalization of the EBERs being exclusively nuclear, while PKR is predominately found in the cytoplasm. Both EBERs have also been shown to activate retinoic acid-inducible gene I protein (RIG-I) and stimulate type I interferon signaling,¹²⁷⁰ but like PKR, RIG-I is generally thought to be a cytosolic protein and the observed interaction was observed via overexpression.

EBV recombinants specifically deleted for the EBER genes have been compared with wild-type recombinants in LCL outgrowth.^{489,1412,1564,1576} In the first experiments, EBER-deleted EBV was equivalent to wild-type EBV in efficiency of primary B-cell conversion to LCLs, in time to LCL outgrowth, in LCL morphology, in LCL regrowth after dilution in fresh medium, or in transition to EBV replication.¹⁴¹² In the later experiments, the efficiency of primary B-cell conversion to LCLs with EBER-restored virus was 20-fold more than that with EBER-deleted virus, LCLs infected with EBER-restored virus grew twice as rapidly as EBER-deleted virus, and LCLs infected with EBER-restored virus grew back after higher dilution than EBER-deleted virus, indicating that EBERs are important in LCL outgrowth.¹⁵⁷⁶ The discrepancy between the two data sets may be due to a complementation effect of the EBER-deleted infected cells by irradiated LCL, which were the source of virus for the LCL outgrowth assays used in the first study. Further studies indicated that deletion of EBER2 is all that is required for the growth defect, suggesting that the EBERs may have different functions.¹⁵⁶⁴ In the most recent studies, the authors observed no significant change in transformation efficiency or growth of LCLs in response to the deletion of the EBERs.⁴⁸⁹ Interestingly, the authors observed changes in the expression of cellular genes in LCLs transformed with EBER deletion viruses. At present, there is not an obvious explanation for the differences observed in transformation efficiency for EBER-deleted virus. It may be related to the methodology used in the various studies or related to the different virus strains utilized in the various studies.⁴⁸⁹

The exact role of the EBV-encoded EBERs is still enigmatic and remains to be determined. The consistent expression of the EBERs in EBV latently infected cells provides a convenient means to identify EBV-infected cells and likely highlights important roles of the EBERs in the biology of EBV infections.

BHRF1, BALF1, BART RNAs, and miRNAs

Early studies had indicated that BHRF1, a virally encoded bcl-2 homolog, is nonessential for *in vitro* transformation of B lymphocytes,^{849,973} can protect cells from apoptosis,^{557,998} and is expressed early in EBV latently infected lymphocytes.^{233,1144} The BHRF1 NMR structure indicates similarity to bcl-2, but BHRF1 differs from bcl-2 in predicted interactions with bax, bak, bid, and bad.⁶²⁵ BHRF1 exerts antiapoptotic effects by binding to Bim,³⁰⁰ VRK2 (human vaccinia virus B1R kinase-related kinase 2),⁸⁷⁴ hPRA1 (human prenylated rab acceptor 1),⁸⁷⁵ Bid, Puma, and Bak.⁸²⁰ Although controversial in function,^{94,408,980} BALF1 has also been shown to block apoptosis,^{408,980} and recent studies have shown that BHRF1 and BALF1 have redundant functions and at least one is required for transformation of newly infected primary B cells *in vitro*.²³ Studies have now shown that BHRF1 is expressed as a latent protein by weak Wp promoter activation in growth-transformed cells *in vitro* using an assay in which BHRF1 is recognized by CD4 T cells⁷³⁸ and functions as a survival factor in the

Wp-restricted Burkitt lymphoma cell line P3HR-1.¹⁵³⁵ Studies have also shown that *cis*-acting effects on RNA processing and Drosha cleavage result in the selective expression of BHRF1 miRNAs, limiting BHRF1 expression in latency 3.¹⁵⁷²

Bam A rightward transcripts, or BARTs, are mRNAs expressed at low levels in all forms of latent and lytic EBV infection *in vitro* and *in vivo*.^{137,207,208,461,462,591,716,868,1163,1261,1405,1621} The BART mRNAs encode BARF0 and RK-BARF0,^{429,759,818} A73,¹³⁶⁷ and RPMS1¹³⁶⁷ proteins, whereas the introns encode microRNAs.^{151,1163} Two TATA-less promoter regions, P1 at nucleotide (nt) 150641 and P2 at nt 150357 in the B95 sequence, likely transcribe the BARTs.^{65,205,294,1367} P1 is active in epithelial cells, is the initial B-cell promoter, and is down-regulated by IRF7 and 5, whereas P2 is more active in epithelial cells and is up-regulated by c-myc and C/EBP.²⁰⁵ BARF0 or RK-BARF0 can interact with Notch receptor cytosolic domains, but the proteins have not been detected in EBV-infected human cells and humans have little detectable antibody to BARF0 or RK-BARF0.^{1448,1487} Similarly, interesting interactions have been described for A73 and RPMS1,¹³⁶⁷ but these proteins have not been detected in EBV-infected cells.

More recent studies, which may be more indicative of the function of the BARTs, have identified a distinct group of about 40 miRNAs encoded by EBV that likely play a critical role in the establishment and/or maintenance of EBV latency and/or contribute to pathogenesis in the human host.^{151,501,1163,1634} Two clusters of miRNAs have been found corresponding to transcripts from the regions of the EBV genome encoding the BHRF1 and BART genes (Fig. 61.2). In general, the BHRF1 miRNAs exhibit expression that is restricted to latency 3 in which Cp/Wp drive EBNA transcription, whereas the BART miRNAs are expressed in all latency types.^{29,151,264,501,763,1163,1573,1634} Induction of lytic replication increases the expression of both the BHRF1 miRNAs^{340,1573} and the BART miRNAs.⁷⁷

Specific EBV miRNA targets identified include the viral DNA polymerase,⁷⁷ LMP1, and LMP2A.^{946,1207} Cellular target proteins include PUMA,²³⁶ CXCL-11,¹⁵⁶⁷ BRCA-1,¹⁶³⁴ stress-induced natural killer (NK) cell ligand MICB,¹⁰⁷² and Bim.⁹⁷⁶ Using immunoprecipitation of RNA-induced silencing complexes (RISCs), the number of potential targets for EBV microRNAs has greatly expanded, with a comprehensive study indicating 44 cellular transcripts may be targeted by EBV miRNAs and 2,337 cellular transcripts are targeted in infected cells.³²⁰ A more recent study used photoactivatable ribonucleoside-enhanced cross-linking and immunoprecipitation (PAR-CLIP) to comprehensively examine the viral and cellular miRNA targetome in B95-8-transformed LCLs¹³⁶¹; 7,827 miRNA interaction sites in 3,492 cellular 3' untranslated regions (UTRs) were identified, of which 531 of these sites contained seed matches to viral miRNAs. A number of the interactions were confirmed by reporter assays. Interestingly, this study also showed that myc-regulated host miRNAs from the miR-17/92 cluster regulate latent viral gene expression.¹³⁶¹

A comprehensive analysis of the function of EBV-encoded miRNAs in B-cell transformation by EBV in which mutations were systematically introduced in the precursor miRNA transcripts encoded by EBV has been done.^{383,1320} In the two studies in which mutations were introduced into the BHRF1 locus to inhibit production of BHRF1 miRNAs, it was found that these miRNAs inhibit apoptosis and favor cell cycle progression and proliferation during the early phase of infected human

primary B cells. This may reduce viral antigenic load at early stages of growth proliferation when other latent genes are not highly expressed.^{383,1320} Studies with BART locus miRNAs did not uncover any gross defect in regard to EBV transformation as monitored in cell culture.¹³²⁰ Compatible with this observation, no defects were found in the regulation of the EBV lytic phase in both studies.^{383,1320} The BART9 miRNA alters LMP1 levels and affects the growth rate of NK T-cell lymphomas.¹²⁰⁷ Interestingly, editing of the BART6 miRNA results in suppression of EBNA-2.⁶⁴⁴ Other studies have suggested that the EBV-encoded miRNA profile in infected cells may differ when normal infected tissues are compared to neoplastic tissues.¹¹⁹³

Finally, EBV-encoded miRNAs and viral-encoded proteins such as LMP1 and gp350 have been found in exosomes released from EBV-infected cells, including nasopharyngeal carcinoma and B cells.^{330,397,481,613,650,750,1006,1146,1485,1498} Interestingly, in peripheral blood mononuclear cells from patients with increased EBV loads, EBV BART miRNAs are present in both B-cell and non-B-cell fractions, suggestive of miRNA transfer.²⁹ Exosomes may manipulate the tumor microenvironment to influence the growth of neighboring cells through the intercellular transfer of virally encoded proteins such as LMP1, signaling molecules, and viral or cellular miRNA.

In addition to miRNAs encoded by EBV, virus infection activates the expression of a number of cellular miRNAs. Most well studied is the enhanced expression of miR-155 by EBV infection or expression of LMP1 that activates NF- κ B and p38/MAPK signal transduction.^{164,328,449,687,786,931,1061,1063,1204,1596} The expression of a number of cellular targets has been studied in the context of EBV up-regulation of miR-155 including c-Myb,⁶⁵⁶ c-Ski,⁶⁵⁶ and components of the BMP signaling pathway.^{1595,1596} Evidence for a direct role in EBV pathogenesis is scant, although some studies indicate direct effects on normal EBV processes such as the expression of EBNA-1 mRNA and the EBV copy number in latently infected cells,⁹³¹ regulation EBV lytic activation,¹⁵⁹⁶ and growth of EBV-transformed LCLs.⁹⁰⁵ This suggests that miR-155 contributes to EBV immortalization by modulation of NF- κ B signaling and the suppression of host innate immunity to latent viral infection. Another cellular miRNA, miRNA200, is decreased in EBV-infected epithelial cells and by transfection of EBV latent genes. Down-regulation of miRNA-200 resulted in down-regulation of E-cadherin expression.¹³³⁷ Other studies with the miR-200 family suggest possible roles in regulating lytic EBV lytic replication in epithelial cells as well in B cells⁸⁹⁴ and in regulating cell growth in nasopharyngeal carcinoma.¹⁶⁰⁹ In regard to regulating EBV lytic replication, studies have shown that miR-200 family members can down-regulate ZEB1 and ZEB2,³⁵⁷ two cellular proteins that repress BZLF1 expression⁸⁰⁴ (see EBV Gene Products Associated With Lytic Replication).

EBV Gene Products Associated With Lytic Replication

BZLF1 and BRLF1

Early studies had shown that various induction strategies could induce lytic replication in a variety of latently infected cells grown in tissue culture. Phorbol esters are among the most reproducible and most broadly applicable inducers of replication.^{37,279,380,402,837,1432,1644} Other agents that can induce lytic replication include calcium ionophore,³⁶⁷ histone deacetylase

inhibitors,⁹⁴² and DNA demethylating agents.⁹⁵ Recent studies have begun to elucidate the signals that result in replication *in vivo*. Early studies suggested that induction of lytic replication may be linked to differentiation of cells harboring latent EBV. Studies of oral hairy leukoplakia found that EBV lytic replication occurred in the outermost differentiated layers of the epithelium.^{1090,1607} More recent studies using B cells have suggested that when B cells differentiate into plasma cells, EBV lytic replication is induced,⁸²⁴ and XBP-1, a plasma cell differentiation factor, is essential for this induction.^{103,1407} Interestingly, down-regulation of BLIMP1- α by LMP1 disrupts plasma cell differentiation, which may be important both in regulating EBV lytic replication and in EBV B-cell lymphomas.¹⁵⁰²

BZLF1 and BRLF1 were identified as transactivators of virus replication as the result of the observation that P3HR-1 Burkitt lymphoma cells replicate and package highly defective EBV that induces lytic infection in Raji cells.^{1020,1022} These viruses express BZLF1 or BRLF1 using the Wp promoter.²⁶⁸ BZLF1 expression in latently infected cells activates EBV replication.^{268,683,684,1020} Compatible with the important role of BZLF1 and BRLF1 expression in inducing lytic replication, both proteins were shown to be expressed after induction of lytic replication following activation of B-cell receptor signaling¹⁴²¹ and found to be essential for activation of lytic replication³⁸² but not important for transformation by EBV of primary B cells.⁷²² Recent studies have shown that cellular expression of early growth response genes are required prior to the expression of BZLF1 and BRLF1 and subsequent activation of lytic replication.¹⁵⁹¹ BRRF1 (also known as Na), which is adjacent to BZLF1 and BRLF1 in the genome, also can induce lytic replication through a TRAF2/JNK-dependent manner in cooperation with p53.^{517,602}

Studies analyzing viral gene expression following induction of lytic replication also established the roles of BZLF1 and BRLF1 as immediate-early viral genes.^{108,1421} More recent studies indicate that BZLF1 is a key inducer of lytic replication as an immediate-early protein^{28,109} but maximal expression of BZLF1 is a result of a BZLF1 autoactivation loop requiring protein synthesis.^{109,399,403,1484,1594} Early promoter regions are coordinately up-regulated by BZLF1 and BRLF1 activating the expression of viral genes involved in replication.^{220,267,269,380,399,425,463,491,496-498,524,600,638,640,745,884,885,1109,1110,1196,1236,1484,1620} Promoter activation has a strong positive effect on DNA synthesis from the lytic origin.¹²⁹⁹ The *cis*-acting domains of early promoters have many similarities including multiple BZLF1- and BRLF1-responsive elements.^{200,220,221,538,880,884,885}

BZLF1 is encoded by a three-exon transcript initiating from the BZLF1 promoter (Zp).⁹⁶⁷ BRLF1 is encoded upstream of Zp and is transcribed in the same orientation as BZLF1 under the control of BLRF1 promoter (Rp).⁹⁶⁷ Rp produces three alternately spliced mRNAs. Two larger transcripts encode BRLF1, whereas the third generates a BZLF1/BLRF1 fusion protein known as RAZ, which is a fusion of the amino terminus of BLRF1 and the BZLF1 DNA binding and dimerization domains.⁹⁶⁷ RAZ is an inhibitor of BZLF1 transactivation and may suppress BZLF1 targets in EBV lytic replication.^{440,1316} BZLF1 and BRLF1 are typically not expressed in EBV latently infected cells.^{1421,1617} The three BZLF1 exons encode a separate functional domain.^{380,882} The first exon encodes amino acids 1 to 167, which transactivate when fused to a Gal4 DNA binding domain.²²² The activating domain can recruit TAFs and

stabilize TFIID association with TATA elements.^{881,883,886} The second exon encodes amino acids 168 to 202, which include a strongly basic domain with homology to a conserved region of the c-fos and c-jun family of transcriptional modulators. This domain confers the ability to interact with AP1-related sites in DNA and targets BZLF1 to the nucleus.¹⁰¹⁶ The third exon encodes amino acids 203 to 245, which include a near-perfect leucine and isoleucine heptad repeat capable of coiled-coil dimer formation.⁴⁰¹ Like c-fos, BZLF1 dimerizes and binds directly to AP1-related sequences. Dimerization may facilitate high-affinity interaction with templates having two or more BZLF1 binding sites.¹⁷⁶ BRLF1 is also a DNA sequence-specific acidic transactivator and has distant homology to c-myc; c-myc can interact synergistically with BZLF1 in transactivating the BMRF1 promoter.^{747,968} Two domains of BRLF1 when fused to the Gal 4 DNA binding domain have transactivating activity for Gal 4 response elements upstream of basal promoters.^{538,539,968} Amino acids 416 to 519 are weakly activating in B cells, while the C-terminal amino acids, 520 to 605, are a potent acidic activator similar to VP16. Similar to BZLF1, the BRLF1 transactivation domain interacts with a number of cellular transcription factors including TBP, TFIIB, and CBP to facilitate promoter activation.^{498,966,968,1414}

BZLF1 contains leucine zipper dimerization motifs.^{401,579,800,882} X-ray crystallography has shown that BZLF1 dimerizes through the leucine zipper, but this dimerization is stabilized by the folding back of amino acids extending beyond the dimerization motif.^{578,1053,1158,1297,1347} This observation may in part explain the inability of BZLF1 to heterodimerize with members of the leucine zipper family of transcription factors.

BZLF1 and BRLF1 are both targets of posttranslational modification. BZLF1 is multiply phosphorylated by casein kinase II, protein kinase A (PKA), and PKC on serines 173, 186, and 336.^{80,278,794} Phosphorylation regulates DNA binding and transcriptional activation. Phosphorylation of S186 in response to PKC activation stimulates transcription but decreases affinity for cognate DNA.⁸⁰

BZLF1 is highly phosphorylated following activation of lytic replication.²⁷⁸ PKC phosphorylates BZLF1 at T159 and S186 and phosphorylation at S186 increases BZLF1 transactivation and DNA replication.^{80,81} T159 is near the activation domain, whereas S186 is in the BZLF1 DNA binding domain. CKII can phosphorylate BZLF1 at S173,⁷⁹⁴ and mutation of this site impairs the ability of BZLF1 to activate lytic replication.^{342,344,345} Other domains within the activation domain of BZLF1 are also phosphorylated, but their function is currently

not known.³⁴⁶ The viral tegument protein BGLF4 phosphorylates BZLF1 and regulates the BZLF1 transactivation function.^{50,51} Both BZLF1 and BRLF1 are modified by sumoylation, which regulates their activities.^{5,7,192,517,1067} BRLF1 sumoylation can be induced by the EBV LF2 protein, which binds BRLF1 and relocalizes BRLF1 to the extranuclear cytoskeleton, resulting in repression of BRLF1 activity.^{153,546}

Regulation of Zp has been studied extensively and contains many *cis*-acting regulatory elements that have been shown to be important in different cellular contexts (Fig. 61.12). Initial studies identified four sequence-related elements termed ZIA, ZIB, ZIC, and ZID and a unique element designated ZII.^{399,402} Two additional sites, ZIIIA and ZIIIB, were also identified that bind BZLF1.³⁹⁹ Further studies found that ZIIIB binds BZLF1 with higher affinity.^{109,399} The ubiquitous transcription factors Sp1/Sp3 bind to the AT-rich ZIA, ZIC, and ZID elements,⁹¹⁰ while the myocyte enhancer factor 2D (MEF2D) binds to the ZIA, ZIB, and ZID elements.⁹¹¹ ZII is a cyclic adenosine monophosphate (cAMP)-response element (CRE)-like motif that binds CREB, ATF family members, C/EBPs, and the AP-1 family of transcription factors.^{6,402,909,1534} Although the ZIA-ZID and ZII elements have distinct DNA sequences and are bound by different regulatory factors, they mediate the induction of lytic virus replication by chemical inducers and BCR cross-linking. Treatment of cells with calcium ionophore and phorbol ester such as TPA induces a rise in intracellular free calcium and activates protein kinase C and is a partial surrogate for Ig cross-linking.²⁷⁹ Ionomycin activates lytic replication through the Ca²⁺-dependent signaling pathway with MEF2D bound to ZIA, ZIB, and ZID and ATF bound to ZII.¹⁹⁶ BCR cross-linking activates phospholipase C- γ . Phospholipase C- γ releases IP₃ and diacylglycerol, which mobilize calcium from intracellular stores and activate protein kinase C, respectively. Elements upstream of the BZLF1 promoter that mediate the Ig cross-linking response include Sp1, Sp3, MEF2D, ATF-1, and ATF-2 sites.^{911,1334} The ATF-1 and ATF-2 binding site is regulated by CAM kinase IV.¹⁹⁶ Inhibition of calcineurin blocks Ig cross-linking-induced EBV activation.¹³⁸

Because the BZLF1 functions as a key switch between latent and lytic replication of EBV, Zp must be tightly repressed to maintain latency. Silencing is achieved by multiple negative regulatory elements^{803,804,909,1612,1625} including elements within ZIIR⁹⁰⁹ and ZV/ZV'^{803,804,1612} Depending on cell type, the cellular proteins ZEB1 or ZEB2 bind to ZV/ZV' to suppress induction of lytic replication^{356,803,804} and a 2-bp mutation in the ZV element results in spontaneously lytic infection.¹⁶¹² The

FIGURE 61.12. Schematic representation of Epstein-Barr virus (EBV) BZLF1 promoter elements. The BZLF1 promoter has a large number of binding sites for regulators of gene expression. Shown in the diagram are the *cis*-acting regulatory elements present within nucleotides -221 through +40 of the BZLF1 promoter relative to the transcription initiation site. Shaded rectangles along the BZLF1 promoter indicate approximate locations of identified regulatory elements with the relevant *trans*-acting factors indicated previously.

cellular microRNAs 200b and 429 can induce EBV latently infected cells to undergo lytic replication by reducing expression of ZEB1/ZEB2.³⁵⁷ The ZRII element of Zp has also been shown to be important for repressing lytic replication by possibly binding a cellular factor.¹⁶¹¹ EBV with mutations within this element is impaired for production of latently infected cell lines and enhanced for lytic replication.¹⁶¹¹ More distal sites from Zp between nt -551 and -222 have also been shown to regulate Zp including a reversible YY1 silencing element.^{909,1040,1041,1311,1442,1616}

A phosphorylated form of MEF2D bound to ZIA, ZIB, and ZID can also repress Zp by recruiting histone deacetylases (HDACs) to maintain chromatin in a repressed state.^{138,1003} A site within ZIIR is a potent silencing element,⁹⁰⁹ and mutations within this element are defective in establishing proliferating latently infected cells and are spontaneous for lytic replication.¹⁶¹¹ The ZIIR is likely targeted by an unknown cellular protein. Studies have identified variants in Zp between malignant and nonmalignant samples from AIDS patients.⁹⁸⁴ Histone acetylation is critical for BZLF1 promoter activation.⁶⁸²

Very recent studies have been particularly informative in understanding how the activation of EBV lytic replication and the establishment of EBV latency are regulated. Methylation of sites within the BRLF1 promoter (Rp) represses the expression of BRLF1, and BZLF1 preferentially binds to these sites.¹⁰⁵ A BZLF1 serine 186 mutant that fully interacts with Zp but is unable to induce lytic replication does not activate Rp and is unable to interact with a methylated Zp.^{8,104,417,418} Structural studies have shown that this serine, along with cysteine 189, interacts with the methyl motif of the CpG dinucleotide.^{715,1298} Studies comparing BZLF1 and BRLF1 deletion viruses²²⁸ and analyzing the temporal order of BZLF1 and BRLF1 expression following induction of EBV lytic replication indicate that BZLF1 is critical in the initial stages of induction of lytic replication.^{228,1539} The importance of DNA methylation in regulating EBV lytic replication is demonstrated in studies indicating that binding of BZLF1 to viral and certain cellular promoters is methylation dependent, allowing BZLF1 to overcome epigenetic silencing.^{98,311,545,1293} Recent studies have suggested that BZLF1 expression early in infection is essential for driving initial proliferation and lytic replication, but initially BZLF1 does not induce lytic replication because the incoming viral genome is not methylated and as a result is not activated by BZLF1.⁷⁰³ Only genomes that are methylated efficiently undergo lytic replication.⁷⁰² Studies using mice reconstituted with human immune systems or SCID mice implanted with LCLs transformed with BZLF1 or BRLF1 mutant viruses demonstrate that expression of BZLF1 or BRLF1 may be important for development of EBV lymphoma.^{603,950,1397}

BZLF1 also interacts with NF- κ B, p53, virion proteins, the human IL-10 promoter and PML bodies and inhibits MHC class I expression.^{92,509,734,957,1319,1624} BZLF1 interaction with PML bodies results in BZLF1 sumoylation and disruption of PML bodies. NF- κ B inhibits BZLF1 transactivation, whereas the interaction of the BZLF1 coiled-coil dimerization domain with the p53 C-terminus transcriptionally inactivates both proteins. BZLF1 inhibition of p53 may be important in preventing p53-induced apoptosis in response to lytic EBV DNA replication. Both BZLF1 and BRLF1 have been found to alter the expression of a variety of cellular genes. This is in part due to high-affinity transcriptional binding sites that

are able to bind BZLF1 and BRLF1. Genes shown to be up-regulated include IL-10,⁹⁵⁷ IL-6, TGF- β ,¹⁸³ EGR-1,¹⁹⁴ c-Fos,⁴⁰⁰ VEGF,⁶⁰⁴ tyrosine kinase TKT,⁹³³ Myc,⁵¹⁰ and matrix metalloproteinases.⁹³⁴ In addition, BZLF1 has been shown to inhibit MHC class I⁷³⁴ and MHC class II expression.⁸⁷⁰ BZLF1 interacts with and directs the degradation of p53 by an interaction with the ECS E3 ubiquitin ligase complex. BZLF1^{1286,1287,1624} also interacts with NF- κ B.^{92,509} Interestingly, it has been reported that BZLF1 can be taken up by cells and reach the nucleus, raising the possibility that BZLF1 may affect transcription in uninfected cells.⁹⁵⁶ BZLF1 and BRLF1 can inhibit induction of IFN- β and expression of IRF3 and IRF7.^{96,518} BZLF1 protein inhibits TNFR1 expression through its effects on cellular C/EBP proteins.¹³² BZLF1 has also been shown to interact with Ku80, which enhances BZLF1 transcriptional activation.²⁰³ Finally, BZLF1 has been shown to induce growth arrest^{182,184,1559} and repress Myc, while Myc expression repressed BZLF1 transactivation.^{896,1235} BRLF1 interacts with Oct-1, which can promote disruption of viral latency¹²³²; this does not require Oct-1 binding to DNA.¹²³²

Other Genes Associated With Early Lytic Replication

Following induction, cells that are permissive for virus replication undergo cytopathic changes characteristic of herpesviruses, including margination of nuclear chromatin,⁷²⁷ inhibition of host macromolecular synthesis,⁴⁵³ replication of viral DNA at the center of the nucleus, assembly of nucleocapsids at the nuclear periphery, nucleation of nucleocapsids, envelopment by budding through the nuclear membrane, and final envelopment at cytoplasmic membranes.^{473,1134,1288} Virus gene expression follows a temporal and sequential order as with other herpesviruses.^{378,1421,1613} The vast majority of genes that are encoded by EBV that are required for lytic replication are conserved within the herpesvirus family and are contained in blocks of genes that are found in different herpesvirus families. Table 61.1 lists the EBV-encoded genes and their HSV and KSHV gene homologs. As can be readily seen, the vast majority of genes that are conserved across these three herpesvirus family members are related to replication, cleavage, assembly, and packaging of the viral genome.

EBV early replicative cycle genes are operationally differentiated from late genes by their persistent transcription in the presence of inhibitors of viral DNA synthesis. By a combination of Northern blot,^{108,379,459,629-631,638,1421} which considers the sensitivity to inhibition of viral DNA synthesis, and array data, which consider the peak time and sensitivity to inhibition of viral DNA synthesis following Ig cross-linking in Akata BL cells, 38 EBV mRNAs are early mRNAs and 40 EBV mRNAs are late mRNAs.^{930,1613} Early and late mRNAs are intermingled through most of the EBV genome. Frequently, different promoters initiate nested transcripts, which begin with different ORFs and terminate at the same polyadenylation site. The longer mRNAs are co-terminal with the shorter mRNAs. Some early and late genes are spliced, while others are not.

BSMLF1

BSMLF1 (SM), also designated EB2 and Mta, is the most rapidly activated early RNA following Ig cross-linking of Akata cells^{1421,1613} and is essential for lytic replication.^{495,528,1258} SM

is the functional homolog of HSV US11 or ICP27. SM is similar to US11 in that it increases the export and levels of most intronless RNAs,^{141,260,746,1221,1257,1259,1317} rather than increasing transcription.^{1085,1259} SM also increases the efficiency of 3' processing and the stability of the EBV DNA polymerase RNA,^{751,1259} which is intrinsically deficient in 3' processing.⁴³⁹ SM amino acids 60 to 140 and 218 to 237 are nuclear export signals,^{126,209} 152 to 172 form an RXP RNA binding domain,^{140,585,1257} and 470 to 474 are core hydrophobic folding residues; the hydrophobic residues and an HX3CX4C motif are conserved in ICP27 and are essential for SM function in replication.¹²⁵⁸ Although SM has broad RNA-binding activity, SM has different affinities for EBV mRNAs⁵²⁹ and different effects on specific EBV messages.¹⁴⁹⁶ A second arginine-rich RNA-binding activity maps to 33 residues C-terminal to the RXP motif and is also essential for SM function.¹²⁵⁸ SM acts as an alternative splicing factor directing donor splice site usage of a cellular gene to a novel alternate 5' site.¹⁴⁹⁷ SM interacts with the splicing factor SRp20, which modulates the activity of SM-directed alternative splicing.¹⁴⁹⁵ Similar to HSV US11, SM binds to and inhibits PKR activation.¹¹⁷⁷ Much of the effect of SM is in rescuing intronless RNA from components of the exon junction complex, in stabilizing the RNAs, and in exporting the RNAs to the cytoplasm. SM interacts with a variety of proteins including cellular RNA-binding proteins, CRM-1, and Sp100.^{126,154,585} SM can also interact with the PML nuclear body component Sp110b and synergize with SM in increasing intronless gene expression.¹⁰⁸⁵

Virus-Encoded Kinases (BXLf1 and BGLf4)

The BGLf4 serine threonine protein kinase, which is homologous to the HSV UL13 and KSHV ORF36, is expressed during lytic replication^{210,454} and is a nuclear protein.^{454,457,1526} It dissociates from the virion in a phosphorylation-dependent manner⁵⁰ and phosphorylates several viral proteins including BMRF1,^{210,455} BZLF1,⁵¹ and EBNA-LP,⁷²¹ as well as cellular proteins including EF-1 γ ,⁷²¹ TIP60,⁸⁷⁸ CKII β ,⁷²⁶ MCM4,⁸⁰⁸ lamin A/C,⁸⁴² stathmin,²¹² and condensin.⁸⁴¹ BGLf4 activates topoisomerase II,⁸⁴¹ and along with its induction of changes in nuclear morphology⁸⁴¹ and modification of the DNA damage response,⁸⁷⁸ these findings suggest that BGLf4 modifies the cell to facilitate virus replication. BGLf4 has an essential role in nuclear egress of capsids from infected cells.⁴⁵⁶ Finally, using EBV mutants in BLGLf4 and BXLf1 (the viral thymidine kinase), BGLf4, but not BXLf1, was shown to be required for ganciclovir or acyclovir inhibition of lytic replication.¹⁰¹⁰ Earlier studies reported that EBV BXLf1 phosphorylates ganciclovir and acyclovir *in vitro*⁹⁰⁶ and enhances cytotoxicity in cells treated with these antivirals,¹⁰⁴⁵ whereas other studies found that BXLf1 poorly phosphorylates ganciclovir and acyclovir^{508,1478} and does not increase cellular cytotoxicity in cells treated with ganciclovir.⁵⁰⁸ These studies highlight the importance of performing studies in the context of virus infection.

DNA Replicative Proteins

EBV early proteins important for DNA replication include the viral DNA polymerase (BALF5), major DNA-binding protein (BALF2), ribonucleotide reductase (BORF2 and BaRF1), thymidine kinase (BXLf1), and alkaline exonuclease (BGLf5) (Fig. 61.2). In addition to its role in DNA replication, BGLf5 mediates host shutoff during productive EBV infection¹²⁴⁷ and

facilitates immune evasion.¹⁶⁴² For further details, see the section on Immune Escape, which describes this and other EBV lytic proteins important for modulating the immune response. The EBV DNA polymerase⁷⁰⁴ is associated with several other EBV nuclear proteins, including the 50-kD processivity factor. The catalytic subunit expressed in insect cells has 3' to 5' proof-reading exonuclease activity in addition to DNA polymerase activity.¹⁴⁷⁵ Unlike cellular polymerases, the EBV polymerase is active in 100-mM ammonium sulfate or in KCl and is sensitive to inhibition by phosphonoacetic acid, phosphonoformic acid, arabinofuranosylthymine, and acyclovir triphosphate.^{19,215,226,285,286,493,1119} The EBV DNA polymerase also differs from HSV DNA polymerase in its salt sensitivity and its relative resistance to aphidicolin. The EBV DNA polymerase also weakly distinguishes between 2-amino-purine nucleoside triphosphate and dATP, so that 2-amino-purine is preferentially incorporated into viral as opposed to cell DNA.⁴⁹³

Considerable progress has been made in reconstituting an *in vivo* minimal DNA replication system similar to the Challenge HSV system.^{395,396} The components include BALF5, which encodes the core DNA polymerase; BALF2, the single-strand DNA-binding protein; BMRF1, the processivity factor; BSLF1 and BBLF4, the primase and helicase complex; BBLF2/3, a spliced primase helicase complex component; and BKRF3, the uracil DNA glycosylase. A surprising aspect of EBV DNA replication is its dependence on expression of the BZLF1 and BRLF1 transactivators.^{395,396} The interaction of the C-terminal tail of BZLF1 with its core leucine zipper is required for DNA replication.¹⁰⁰⁴ In addition, mutations in the BZLF serine 173 phosphorylation site and DNA recognition domain are competent for the induction of early lytic genes but have a reduced capacity to bind DNA and activate lytic DNA replication; however, overexpression of BSLF1, BMRF1, and BALF2 partially restores DNA replication and binding to oriLyt.^{342,343} EBV DNA replication requires topoisomerase 1 and 2 activity.^{728,1004} EBV DNA replication induces growth arrest indirectly by activation of a DNA damage response.^{809,810}

DNA Packaging and Virion Egress

The EBV TR has several similarities to the HSV "a" sequence.^{1038,1379} Both EBV TR and the HSV "a" sequence are directly repeated at both ends of the DNA. Both sequences are high in G+C composition, with runs of three to five Cs. In both HSV and EBV, there is a short extra oligonucleotide segment (DR1) where the repeat joins the unique DNA. The EBV DR1 oligonucleotide GCATGGGGGG brackets the multiple copies of TR. In HSV-1, DR1 is the site of cleavage of headful length DNA for packaging into virions. There is little sequence specificity for DR1 because the nonhomologous oligonucleotides of HSV-1, HSV-2, and CMV are interchangeable. HSV or CMV cleavage and packaging occur 33 base pairs 3' to a conserved sequence of C(G)₆₋₈ TGT G/T (T)₃ NG C/G (G)₆ G/C T/C. A similar sequence C (G)₅ TGT(T)₂ CCT(G)₅ CC occurs 25 base pairs before the EBV DR1 and is also the key cleavage packaging recognition sequence for EBV. The EBV rightmost TR acquires a short unique sequence from the leftmost TR during cleavage and packaging, and that sequence becomes the left end of the DNA.¹⁶³⁸ Plasmids containing the EBV latent infection episome origin, the EBV lytic origin, and the EBV TR are stably maintained as an episome in latently infected cells, are replicated as linear concatemers by the EBV DNA polymerase when

lytic infection is induced, and are cleaved and packaged into infectious virions.¹⁵²³

Early electron microscope observations of lymphocytes lytically infected with EBV report the presence of nucleocapsids in the cytoplasm. While this could occur as a consequence of nuclear disruption late in infection or as a consequence of reinfection of the infected cell by released virus, an alternative model is that virus acquires an initial envelope as it buds through the nuclear membrane, that de-envelopment occurs within cytoplasmic vesicles resulting in release of nucleocapsids into the cytoplasm, and that re-envelopment occurs prior to release of infectious virus as postulated for other herpesviruses. BFLF2 and BFRF1 are positional homologs of UL31 and UL34 of HSV and are essential for the egress of newly assembled capsids across the nuclear membrane in HSV. Deletion of BFLF2 from EBV impairs virus egress but does not affect lytic DNA replication or B-cell transformation.^{474,483} Interestingly, the BFLF2 deletion virus has a further defect in DNA packaging, suggesting there may be some divergence in the function of this protein in herpesviruses.^{474,483} As in other herpesviruses, EBV gM and gN are important for egress of EBV virions from infected cells. These two proteins form a stable complex in infected cells, and EBV that lacks gN is deficient in envelopment and de-envelopment.^{827,828}

ENTRY INTO HOST: PORTALS OF ENTRY, SITE OF PRIMARY REPLICATION, CELL TYPES INFECTED

Most EBV infections occur through contact with infected saliva from persons infected in the past. Saliva contains virus that is high in EBV gp42, indicating that the virus is derived predominantly from MHC class II–negative cells (i.e., epithelial cells rather than B cells).⁶⁸⁹ Virus in saliva is more efficient in binding B cells than epithelial cells. During primary infection, EBV infects epithelial cells in Waldeyer's ring in the oropharynx where it replicates¹³⁵⁴ and then can infect resting naïve B cells that traffic through the oropharynx, or may infect resting, naïve B cells in the tonsillar crypts directly (Fig. 61.13).^{246,714} Virus replication has been found in rare tonsillar epithelial cells⁶²⁸ and in epithelial cells during infectious mononucleosis (IM)⁸⁵⁸; in contrast, other studies have reported replication only in B cells in the tonsils.³² While some B cells undergo lytic infection,

most become latently infected. Initially the cells are lymphoblasts with a type 3 pattern of latency and express each of the EBV latency genes^{32,817} (Table 61.2). Up to 10% of B cells in the blood early in infection are EBV positive. Most of these cells are thought to be killed by NK cells, antibody-dependent cell-mediated cytotoxicity (ADCC), or cytotoxic T cells.

A controversy exists as to whether EBV-infected B cells mimic the pathway in which naïve B cells differentiate to become resting memory B cells. Thorley-Lawson and colleagues^{912,1445} postulate that EBV-infected naïve B cells enter germinal centers and differentiate to resting memory B cells, similar to the process in which naïve B cells are activated by antigen to become B-cell blasts; enter the germinal center of lymphoid follicles; undergo class switch recombination and somatic hypermutation; and subsequently differentiate into resting memory B cells (Fig. 61.14). Only B cells whose surface immunoglobulin (B-cell receptor) has a high affinity for antigen avoid apoptosis and become CD27+ memory B cells. Similarly, naïve B cells infected with EBV express EBV type 3 latency genes resulting in B-cell proliferation and blast formation. These cells then migrate to a lymphoid follicle to begin the germinal center reaction. EBV-infected cells then express EBV latency 2 genes. EBV LMP1 up-regulates activation-induced cytidine deaminase (AID) to induce somatic hypermutation or immunoglobulin class switching.⁵⁴² EBV LMP2A stimulates antigen receptor signaling.¹⁵⁶ This allows the cell to survive its transit through the germinal center.

Upon exiting the germinal center into the blood, the virus-infected cells differentiate into memory B cells and express the EBV latency 0 pattern of gene expression with no viral proteins expressed.⁵⁹⁶ Some of the cells may undergo differentiation to plasma cells with EBV lytic replication, and the resulting virus can infect naïve B cells. Other EBV-infected B cells are thought to traffic back to the oropharynx, where they can undergo differentiation into plasma cells and either shed virus into the saliva directly or infect epithelial cells, which shed EBV into the saliva.

Several lines of evidence suggest that EBV-infected B cells may not always follow this pathway of infecting naïve B cells, transiting germinal centers, and trafficking to the oropharynx. First, EBV can infect both naïve and memory B cells.^{341,817} Second, EBV is present in both non-isotype-switched and isotype-switched memory B cells¹⁸⁹; the latter are thought to be independent of the germinal center. Third, EBV-infected B cells are usually in extrafollicular areas rather than the germinal

TABLE 61.2 EBV Latency Gene Expression Patterns

Latency	EBERs	EBNA-1	EBNA-2	EBNA-3	EBNA-LP	LMP1	LMP2	BARTs	Disease
0	+	— ^a	—	—	—	—	—	?	Blood in healthy carriers
1	+	+ ^b	—	—	—	—	—	+	BL, gastric carcinoma
2	+	+ ^b	—	—	—	+	+	+	NPC, HL, TCL
3	+	+ ^c	+	+	+	+	+	+	PTLD

^aEBNA-1 is expressed only when cells divide.

^bEBNA-1 is driven by the BamH1 Qp promoter.

^cEBNA-1 is driven by the BamH1 Cp or BamH1 Wp promoter.

EBER, Epstein-Barr virus–encoded RNA; EBNA, Epstein-Barr virus nuclear antigen; LMP, latent membrane protein; BL, Burkitt lymphoma; NPC, nasopharyngeal carcinoma; HL, Hodgkin lymphoma; TCL, T-cell lymphoma; PTLD, posttransplant lymphoproliferative disease.

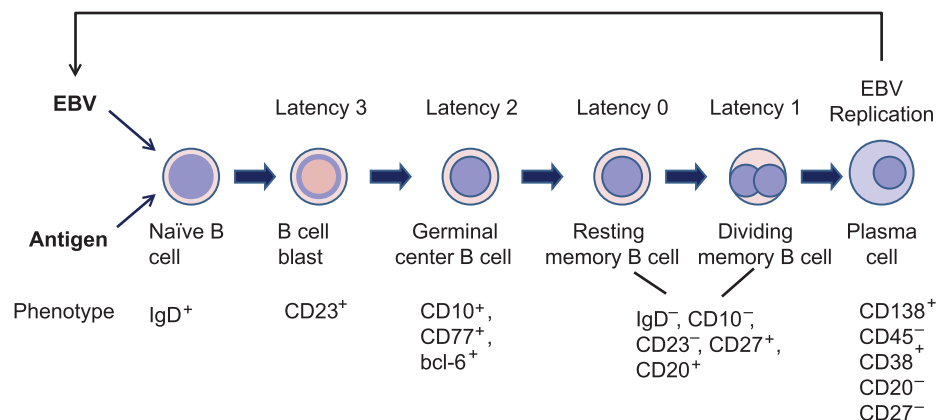

FIGURE 61.13. Epstein-Barr virus (EBV) life cycle. EBV infects resting B cells either directly or by virus released from epithelial cells in the oropharynx. EBV-infected B cells in the lymphoid tissues and blood undergo lytic infection or become B-cell blasts, which are controlled by NK cells and cytotoxic T cells. Latently infected resting memory B cells express no viral proteins unless they divide; if they reactivate, they are controlled by cytotoxic T cells. Some latently infected cells traffic to the oropharynx where they undergo lytic replication and release virus. (Adapted from Cohen JI. Epstein-Barr virus infection. *N Engl J Med* 2000;343[7]:481–492.)

FIGURE 61.14. Epstein-Barr virus (EBV) infection of B cells parallels the response of B cells to antigenic stimulation. EBV infects naïve B cells, which become B cell blasts with type 3 EBV latency. The cells undergo a germinal center reaction with type 2 EBV latency and exit the germinal center with type 0 EBV latency. EBV-infected resting memory B cells can differentiate in plasma cells whereby EBV undergoes lytic replication and can infect new naïve B cells.

centers.^{817,1089} Fourth, patients with X-linked lymphoproliferative disorder (XLPD) have absent or poorly formed germinal centers,⁹⁴⁹ but they are infected with EBV (see later). Patients with X-linked hyperimmunoglobulin M syndrome lack classical memory B cells and their B cells cannot undergo a germinal center reaction and therefore are not class switched (IgD[−], CD27⁺); however, these patients can be infected with EBV.²⁵⁷ These patients have EBV in nonclassical memory B cells (IgD⁺, CD27⁺). Therefore, germinal center reactions and classical memory B cells are not necessary for EBV infection. Fifth, EBV-infected B cells in the tonsils express the CD10 and CD77 germinal center markers in some¹²⁴³ but not other¹⁸⁹ studies. Thus, EBV-infected cells may not require transit through the germinal center. Sixth, EBV-infected B cells in the germinal center may not participate in germinal center reactions during IM.⁸¹⁶ Seventh, EBV-infected B cells in tissues have a wide variety of expression of EBV latency proteins with patterns other than latency patterns 0 to 3.⁸¹⁷ Thus, another model posits that EBV infects and proliferates in memory B cells and that the germinal center reaction is not essential.⁸¹⁴ Finally, virus shedding still occurs in the absence of detectable B cells in the peripheral blood,⁶⁰⁵ which indicates either that other cells can also transport EBV to the oropharynx or that EBV is maintained in B cells in the oropharynx in the absence of B cells in the periphery.

While EBV infects naïve and memory B cells from tonsils *ex vivo*, EBV is less efficient in infecting memory B cells from the blood.³²⁵ IgA-positive or IgG-positive memory B cells from the tonsils are infected more efficiently with EBV than IgM memory B cells from the tonsils. EBV infects memory B cells in nasal-associated lymphoid tissue more efficiently than memory B cells in other lymphatic tissues; β 1 integrin on the memory B cells in nasal-associated lymphoid tissue increases the susceptibility of these cells to EBV infection.³²⁵ EBV has been detected in plasmacytoid B cells.³²

B cells are essential for EBV latency. Persons with X-linked agammaglobulinemia who lack mature B cells are not infected with EBV and have no cellular immunity to EBV.³⁸¹ Hematopoietic stem cell transplantation, which eliminates host B cells but not epithelial cells, can eliminate EBV from the body.⁴⁸⁵ In addition to B cells, EBV infects epithelial cells. EBV replication is detected in epithelial cells of the tongue but not in epithelial cells of the salivary glands.^{419,1508} EBV also infects human umbilical cord–derived endothelial cells.⁶⁹⁹

While EBV is present in B cells in the blood of healthy individuals, in some patients with elevated EBV levels in the blood (e.g., patients with HIV, transplant recipients), EBV has been detected in other cell types, usually at a lower frequency than in B cells. EBV has been detected in the blood in cells other than B cells including CD4 and CD8 T cells in patients with HIV,⁸⁹ γ/δ T cells, and NK cells in patients with chronic active EBV disease⁷⁷⁰; plasmablasts/plasma cells and monocytes in patients with lymphoproliferative diseases and HIV^{152,1476}; and pre-Langerhans cells in the blood of persons with HIV as well as healthy individuals.¹⁵¹¹

IMMUNE RESPONSE

Innate Immune Response

The innate immune response includes interferon responses and NK cells. Herpesvirus nucleic acids are detected by TLRs and

RIG-I, which in turn activate a number of adapter molecules, including IRFs, which lead to expression of IFN- α and IFN- β . These bind to IFN receptors and activate expression of interferon-stimulated genes (ISGs).

Treatment of monocytes with EBV DNA or virus stimulates release of IL-8 through TLR2 and TLR9, while release of MCP-1 and IL-10 was mediated primarily by TLR2.³⁹² EBV BLLF3 (dUTPase) activates NF- κ B through TLR-2 and induces expression of proinflammatory cytokines.⁴⁷

Expression of EBERs activates RIG-I and IRF-3 and induces expression of IL-10.¹²⁷¹ Expression of EBERs in cells expressing RIG-I induces expression of type I IFN and ISGs; this requires NF- κ B and IRF-3.¹²⁷⁰ EBERs are transcribed by RNA polymerase 3, which then triggers RIG-I activity.⁴ EBER1 is released from virus-infected cells in a complex with the cellular protein La and activates TLR3 to induce expression of IFN- β , IFN- γ , and TNF- α .⁶⁶³

EBV up-regulates expression of TLR7; treatment of B cells with UV-irradiated virus and a TLR7 ligand enhances B-cell proliferation.⁹⁸² In contrast, EBV lytic infection down-regulates TLR9. CpG increases proliferation and transformation of EBV-transformed B cells and increases T-cell co-stimulatory molecules, up-regulation of IL-6, and release of virus from lymphoblastoid cell lines.⁶⁵⁹ TLR2 or TLR7/8 ligands also enhance EBV-induced B-cell transformation.

Incubation of plasmacytoid dendritic cells with EBV or viral DNA results in release of IFN- α through TLR9.³⁹² LMP1 up-regulates expression of ISGs, which induces an antiviral effect.¹⁶²²

NK cells are important for early control of EBV. Patients with X-linked lymphoproliferative disease have impaired NK-cell killing, which contributes to fulminant primary EBV infection observed in many patients. NK cells from the tonsils produce high levels of IFN- γ and inhibit EBV transformation.¹³⁹⁶ IFN- γ from NK cells also delays latent EBV antigen expression in virus-infected cells and reduces B-cell proliferation during the first 7 days of infection *in vitro*.

NK-cell numbers are increased at the onset of IM and have enhanced ability to kill virus-infected cells.¹⁵⁴¹ During IM, higher NK-cell counts are associated with a lower viral load in the peripheral blood. Cytokines that regulate NK-cell activation (IFN- α , IFN- β , IFN- γ , and IL-12) are significantly increased in persons with IM compared with healthy controls.

Antibody Response

Antibody is likely important for protection against IM but may not be sufficient to prevent infection; vaccine trials using gp350 as an immunogen showed reduction of IM but no difference in infection.¹³⁶⁹ Initial control of EBV infection is due to NK cells and non-HLA-specific cytotoxic T cells, while later during convalescence HLA-specific CD8 and CD4 T cells are important for control of infection (see Cellular Immunity below).

Acute EBV infection induces polyclonal B-cell activation with elevated levels of IgG, IgM, and IgA. Heterophile antibodies are produced, which are not EBV specific. One type of heterophile antibody, used for diagnosis of acute infection, measures the dilution of serum that agglutinates sheep, horse, or cow erythrocytes after absorption with guinea pig kidney. Heterophile antibodies persist for up to 1 year after IM and are often absent in children younger than 5 years old or in the elderly.

FIGURE 61.15. Pattern of antibodies to Epstein-Barr virus (EBV) during acute infection. (From Cohen JL. Epstein-Barr virus. In: Young NS, Gerson SL, High KA, eds. *Clinical Hematology*. Philadelphia: Elsevier, 2006:956–966, copyright © 2006 Elsevier.)

In addition to heterophile antibody, IgM and IgG antibodies to the viral capsid antigen (VCA) are usually present at the onset of symptoms of IM (Fig. 61.15).²⁴⁷ Later in infection, antibody to EBNA is detected and IgM antibody to VCA disappears. IgG antibody to VCA²⁵ and EBNA persists for life. Antibodies to EBV early antigens (EAs) are classified as either diffuse (EA-D, diffusely in the nucleus and cytoplasm, methanol resistant) or restricted (EA-R, restricted to the cytoplasm, methanol sensitive). EA-D antibodies are often present 3 to 4 weeks after the onset of IM, especially in patients with severe illness, and are frequently detected in patients with nasopharyngeal carcinoma (NPC) or chronic active EBV (CAEBV). EA-R antibodies are often detected in CAEBV or African BL. IgA antibody to EBV is often elevated in patients with NPC, and IgA antibody to EBV EA is present in patients with IM.¹⁰¹

Cellular Immune Response

Acute Infection

During IM there is a massive expansion of CD8, but not CD4, T cells.⁹⁵⁹ Monoclonal or oligoclonal populations of CD8 T cells (based on T-cell receptors) are present, which react with EBV latent antigens,^{160,959} but there are not clonal populations of CD4 T cells. Oligoclonal populations of CD8 T cells may also be present that react with EBV lytic epitopes.³⁸

Most EBV-specific CD8 T cells have an activated memory phenotype and express HLA-DR and CD45RO with down-regulation of CD63L and CD45RA.¹⁶¹ Cytotoxic T cells to lytic and latent antigens during IM display a CD45RO+, CCR7– effector phenotype; later lytic antigen responses have either a CD45RA+, CCR7–, or a CD45RO+, CCR7– effector memory phenotype, while latent antigen responses have either a CD45RO+, CCR7+ central memory phenotype or a CD45RO+, CCR7– effector memory phenotype.⁵⁸⁶ CD8 T cells during IM have cytotoxic activity and contain perforin^{159,1389,1390}; most of the cells have a very short lifespan and undergo apoptosis when the level of EBV antigen declines.^{159,331,1422} During convalescence the frequency of EBV-specific T cells declines and in long-term carriers up to 5% of cytotoxic T lymphocytes (CTLs) are directed against EBV antigens.⁵⁸⁶ Expression of programmed death receptor 1 (PD1, a marker of lymphocyte exhaustion) is elevated on EBV-specific CD8 T cells during IM, correlates with the EBV viral load, and returns to low levels during convalescence.⁴⁸⁷

Initially CD8 T cells are directed predominantly against EBV lytic antigens; later in infection cytotoxic T cells are

directed to latent antigens⁵⁸⁶ (Fig. 61.16). CD8 T cells to additional latent antigens may arise 3 to 4 months after acute infection.^{586,1554} Up to 44% of CD8 T cells can recognize a single lytic epitope during IM in some persons.^{161,1188,1389,1390} While the level of CTLs to EBV immediate-early (IE) antigens declines rapidly after infection, the level of CTLs to latency proteins declines much more slowly. Of the lytic antigens, CD8 T cells recognize IE proteins (BZLF1, BRLF1) more often than early proteins (BMRF1 and BMLF1), and late proteins least frequently.^{1188,1389} (Fig. 61.17). This hierarchy of IE over E proteins may be due to expression of immune evasion genes that block CD8 T-cell responses later in the lytic replication cycle. There is a direct correlation between CD8 T-cell immunodominance among the lytic antigens and the efficiency with which these antigens are processed and presented to CD8 T cells in lytically infected cells.¹¹⁸⁸ Up to 5% of CD8 T cells are directed to latent antigens, especially EBNA-3A, -3B, and -3C.^{161,1389}

CD4 T-cell responses to EBV proteins have been less well studied than CD8 T-cell responses, especially in IM. CD4 T cells from patients with IM recognize EBNA-3C to a greater extent than EBNA-1 or EBNA-2, while EBNA-1 is predominant in long-term carriers.¹⁵⁵⁴ During IM, CD4 T-cell responses to BZLF1 are higher than CD8 T-cell responses.¹³⁰¹ CD4 T cells recognize BZLF1, BMLF1, and EBNA-3A in patients with IM and the responses rapidly decline after acute infection to less than 1% at 1 year.¹¹⁸⁴ While the CD8 T-cell response favors IE over early EBV proteins, the CD4 T-cell response is distributed more equally to IE, early, and late viral proteins.⁹¹⁶ These findings are consistent with CD8 T-cell expansions being induced by direct contact with IE antigens on lytically infected cells before MHC class I immune evasion proteins encoded by EBV are expressed, while CD4 T-cell expansions are due to multiple antigens released from infected cells and presented to CD4 T cells by dendritic cells.

While there are large numbers of EBV-specific T cells in the blood during IM, relatively few of these T cells traffic to the tonsils.⁵⁸⁷ CD8 T cells that recognize lytic antigens are fourfold more prevalent in the tonsils than in the blood, and CD8 T cells that recognize latent antigens are 10-fold more prevalent in the tonsils.⁵⁸⁷ CD8 T cells that recognize EBV lytic and latent epitopes in the blood of patients with IM have low levels of the lymphoid homing receptors CCR7 and CD62L.^{161,331,586,587} While CD8 T cells in the blood that recognize latent antigens may be CCR7+ and CD62L+ and accumulate in the tonsil

FIGURE 61.16. Levels of Epstein-Barr virus (EBV) in the throat and blood and cellular immunity during the course of infection. (From Hislop AD, Taylor GS, Sauce D, et al. Cellular immunity responses to viral infection in humans: lessons from Epstein-Barr virus. *Annu Rev Immunol* 2007;25:587–617, with permission.)

FIGURE 61.17. CD8+ and CD4+ T-cell responses to Epstein-Barr virus (EBV) immediate-early (IE), early (E), late (L), and latent proteins. (From Hislop AD, Taylor GS, Sauce D, et al. Cellular responses to viral infection in humans: lessons from Epstein-Barr virus. *Annu Rev Immunol* 2007;25:587–617, with permission.)

after IM, CD8 T cells that recognize lytic antigens remain CCR7[−] and CD62L[−] much longer after IM. This might allow virus-infected cells in the tonsil to undergo persistent lytic replication. In long-term carriers, the tonsils show a 10- to 20-fold enrichment of T cells that recognize latent epitopes and a 2- to 5-fold enrichment of T cells that recognize lytic epitopes compared with the peripheral blood.⁵⁸⁷ The CD38 B-cell activation marker is present on CD8 T cells that recognize lytic or latent EBV epitopes in the blood during IM but is down-regulated during convalescence.^{181,586}

Healthy Carriers

In healthy carriers, the frequency of EBV-specific CD8 T cells is about 0.2% to 2% for viral lytic proteins and 0.05% to 1% for latent proteins and remains stable over time.⁵⁹⁰ In healthy carriers CD8 T cells predominantly recognize the EBNA-3A, -3B, and -3C latency proteins.^{754,1070} IE BZLF1 and BRLF1, and early BMRF1 and BMLF1 proteins are also prominent targets of CD8 T cells.⁵⁸⁶ Other EBV early (BALF2, BALF5, BGLF4) and latency (LMP2 and to a lesser extent EBNA-1 and EBNA-2) proteins are also targets for CD8 T cells; late proteins are less frequently targeted. Clonal expansions of EBV-specific CD8 T cells contract over time but do persist and have cytotoxic activity.^{867,1341,1342} EBV-specific cytotoxic CD8 T cells are perforin(−/+), granzyme (Grm) B(+), GrmA(+), and GrmK(+); perforin and GrmB, but not GrmA and GrmK, correlated with cytotoxic activity.⁵³⁷

The frequency of CD8 T cells that recognize EBV proteins is 10-fold higher in healthy EBV carriers than for CD4 T cells.^{855,915} CD4 T cells predominantly recognize EBNA-1 (especially the carboxyl terminus) in healthy EBV carriers, and to a lesser extent EBNA-2 and EBNA-3C.^{550,855,1472} EBNA-1 can be recognized by endogenous processing in the proteasome.^{1434,1501} EBNA-1 accumulates in cytoplasmic autophagosomes where lysosomal processing enhances EBNA-1 recognition by CD4 T cells.¹¹²⁹ Studies using B cells with inducible expression of EBNA-1 and EBNA-3B showed that CD8 T cells recognized the latency proteins rapidly but that recognition declined quickly when protein expression was suppressed; in contrast, CD4 T-cell recognition was delayed when latency protein expression was induced but persisted for days after protein expression was suppressed.⁹⁵³ These results imply that *de novo* EBV-infected cells are recognized predominantly by CD8 T cells, while latently infected cells are better recognized by CD4 T cells.

Other latency (EBNA-3A and -3B, LMP1, and LMP2) as well as multiple IE, early, and late lytic proteins (BZLF1, BMLF1, BHRF1, BNLF2b, BCRF1, gp110 [BALF4], gp350 [BLLF1]) are recognized by CD4 T cells from healthy carriers,⁹ although the relative frequencies of individual IE, early, and late proteins are not known. The broad array of latency proteins recognized by CD4 T cells is presumably due to CD4 cells recognizing antigens released from infected cells, rather than by direct contact with cells expressing latency proteins. *In vitro* studies show that gp110 and gp350 antigen is transferred to B cells by uptake of virions, resulting in MHC class II presentation of the glycoprotein antigens to CD4 T cells that are cytolytic and inhibit proliferation of virus-transformed B cells. EBNA-2 and EBNA-3C are thought to be recognized by CD4 T cells upon transfer of antigen of these EBV proteins between cells, rather than processing by autophagy.¹⁴³¹

EBV-specific CD4 T cells produce IFN- γ and TNF- α but less frequently produce IL-2 in response to antigen.³⁰ Some EBV-specific CD4 T-cell clones are cytotoxic or inhibit outgrowth of virus-transformed cells, while others do not.⁹¹⁵ Most EBV-specific CD4 T cells express CD27 and CD28.

Immune Escape

EBV uses a number of strategies to avoid detection by the immune system. Activation of EBV replication, which allows the immune system to detect viral proteins, results in down-regulation of MHC class I, class II, and β_2 -microglobulin with impaired antigen presentation by virus-infected cells.^{504,734} Activation of virus replication increases the susceptibility of virus-infected cells to killing by NK cells, which corresponds to down-regulation of HLA-A, B, and C (which bind to KIR inhibitory receptors on NK cells) and down-regulation of HLA-E (which binds to the NKG2D inhibitory receptor).¹¹³³ EBV inhibits dendritic cell development by inducing apoptosis of monocyte precursors.⁸⁷³ EBV encodes a number of proteins that help the virus to avoid killing of infected cells by the immune system.¹²¹⁸

The EBNA-1 Gly-Ala repeats were initially reported to inhibit processing of EBNA-1 by the proteasome and presentation of EBNA-1 peptides to CD8 T cells.^{865,866} (Table 61.3). More recent studies indicate that the dominant role of the EBNA-1 Gly-Ala repeats is to reduce the translation efficiency of EBNA-1, resulting in fewer EBNA-1 peptides expressed on the surface of cells, which results in less efficient recognition by EBV-specific CD8 T cells.^{1435,1597} Newly synthesized EBNA-1, rather than long-lived stable EBNA-1, is the primary source of the protein's epitopes that are presented to CD8 T cells.^{1434,1501}; this suggests that defective ribosome EBNA-1 products may be the major source of EBNA-1 epitopes. The mRNA that encodes the EBNA-1 Gly-Ala repeats is enriched for purines, which results in a lack of secondary structure, inhibits the efficiency of protein translation, and reduces antigen presentation.¹⁴³⁶ The EBNA-1 Gly-Ala repeats also inhibit translation initiation of EBNA-1 mRNA,⁴² and the rate of inhibition of translation correlates with reduced antigen presentation of EBNA-1.⁴¹ EBNA-1 inhibits pre-mRNA processing of its transcripts, resulting in autorepression of EBNA-1 in latently infected cells, which may reduce the level of protein available for detection by the immune system.¹⁶⁰² While presentation of some CD4 epitopes from EBNA-1 requires autophagy,¹¹²⁹ localization of EBNA-1 to the nucleus limits its processing by autophagy and its presentation to CD4-specific T cells.⁸⁶⁰ Regardless of these findings, EBNA-1 is recognized by CD8 T cells.^{851,1434,1501}

LMP1 inhibits its presentation to MHC class I by self-aggregation and possible destruction of LMP1 epitopes in proteasomes.¹³⁶⁶ LMP1 levels in EBV-infected cells vary over time, and this may allow cells expressing low levels of the protein to avoid killing by CD8 T cells.¹³⁵ LMP1 peptides suppress T-cell activation, inhibit T-cell proliferation, and reduce NK-cell cytotoxicity; however, it is not clear if such peptides are present and at levels required to have immunosuppressive activity.³³⁰ LMP1, secreted in exosomes from virus-infected cells, inhibits T-cell proliferation.^{397,750} LMP2A and LMP2B increase the degradation of IFN receptors in epithelial cells, which may limit the antiviral response in virus-infected cells.¹³²⁴ LMP1 and LMP2A up-regulate the galectin-1 promoter; galectin-1 triggers apoptosis of EBV-specific cytotoxic T cells.¹¹²³

TABLE 61.3 EBV Proteins and RNAs that Inhibit the Immune System

EBV protein	Effect
EBNA-1	Inhibits its own proteasome processing Reduces its own translational efficiency and initiation of translation
LMP1	Up-regulates galectin promoter to induce apoptosis of CTLs Up-regulates IL-10, up-regulates A20 and bcl-2 to inhibit apoptosis
LMP2	Increases degradation of IFN receptors Up-regulates galectin promoter to induce apoptosis of CTLs
BARF1	Soluble colony-stimulating factor receptor, inhibits IFN- α secretion
BCRF1	IL-10 homolog; inhibits synthesis of IFN- γ by T cells; reduces MHC class II expression; reduces IL-1 α , IL-1 β , TNF- α , and IL-6 production in monocytes; reduces levels of MHC class I, ICAM1, CD80, and CD86 on monocytes; reduces mRNA levels of TAP1 and proteasome protein LMP2
BGLF5	Blocks synthesis of MHC class I and II molecules Down-regulates TLR9
BHRF1	Bcl-2 homolog, blocks apoptosis
BILF1	Binds MHC class I molecules and removes MHC class I from cell surface Reduces rate of newly synthesized class I molecules on the cell surface by diverting them from the exocytic pathway Forms heterodimers with CXCR4 and impairs binding to CXCL12
BLLF3 (dUTPase)	Up-regulates IL-10, TNF- α , IL-1 β , IL-8, and IL-6
BNLF2a	Interacts with TAP, inhibits its ATP and peptide-binding functions, reduces MHC class I at the cell surface
BZLF1	Up-regulates IL-10; inhibits IRF7 (and type I IFN); inhibits IFN- γ -induced MHC class II expression; inhibits activation of IRF1, CIITA, and p48 and nuclear translocation of STAT1; decreases levels of IFN- γ receptor- α mRNA and level of TNF receptor 1
BZLF2 (gp42)	Binds the HLA-DR β chain of class II and inhibits antigen presentation, inhibits generation of CTLs in mixed lymphocyte reactions
LF2	Inhibits dimerization of IRF7, inhibits IFN- α production
EBV RNA	
EBER	Up-regulates IL-10, induces resistance to IFN- α -mediated apoptosis
miR-BART2-5P	Reduces expression of MICB, a stress-induced NK-cell ligand, to reduce killing by NK cells
miR-146a	Inhibits expression of IFN-responsive genes

EBV, Epstein-Barr virus; EBNA, Epstein-Barr virus nuclear antigen; LMP, latent membrane protein; CTL, cytotoxic T lymphocyte; IL, interleukin; IFN, interferon; MHC, major histocompatibility complex; TNF, tumor necrosis factor; ATP, adenosine triphosphate; mRNA, messenger RNA; HLA, human leukocyte antigen; NK, natural killer.

EBV BNLF2a co-localizes with the transporter associated with antigen processing (TAP) in the endoplasmic reticulum and is expressed early in infection.⁶¹⁰ BNLF2a interacts with TAP and inhibits its adenosine triphosphate (ATP) and peptide-binding functions and reduces MHC class I at the cell surface, resulting in inhibition of CD8 T-cell recognition of antigens on target cells.^{589,1565} BNLF2a is expressed early in the lytic cycle of EBV replication and it affects presentation of IE and early EBV proteins, but not late proteins.²⁷² Nonetheless, CD8 T-cell clones can lyse lymphoblastoid cells expressing BNLF2a.⁸²⁹

The EBV host shutoff function of BGLF5 down-regulates MHC class I expression and inhibits virus-specific CD8 T-cell recognition of endogenous antigens by MHC class I.¹⁶⁴² BGLF5 blocks synthesis of both MHC I and II molecules¹²⁴⁷ and down-regulates TLR9.¹⁴⁹⁰

BILF1, a constitutive G protein-coupled receptor, binds to MHC class I molecules, resulting in increased turnover of MHC class I from the cell surface and increased degradation by lysosomes.¹⁶⁴⁰ The G protein signaling activity of BILF1 is independent of its effect on MHC class I. BILF1 also reduces the rate of newly synthesized class I molecules on the surface by diverting them from the exocytic pathway. The effect of BILF1

on the exocytic pathway accounts for about 70% of its immune evasion activity.¹⁶⁴¹ Deletion of BILF1 from the virus increases recognition of virus-infected cells by CD8 T cells. BILF1 also forms heterodimers with various chemokine receptors,¹⁴⁹⁹ and binding of BILF1 to CXCR4 impairs the latter's binding to CXCL12 and reduces CXCL12 signaling.¹⁰⁹²

EBV BCRF1 shares 70% amino acid identity with human IL-10 and, like its human homolog, BCRF1 inhibits synthesis of IFN- γ by T cells.^{621,1044} BCRF1 reduces MHC class II expression on monocytes, resulting in both reduced antigen presentation and antigen-specific T-cell proliferation.²⁹⁵ BCRF1, like human IL-10, reduces IL-1 α , IL-1 β , TNF- α , and IL-6 production in monocytes. BCRF1 also reduces levels of MHC class I, ICAM1, CD80 (B7.1), and CD86 (B7.2) on monocytes.¹²⁶⁸ BCRF1 reduces mRNA levels of TAP1, and LMP2 (low molecular mass polypeptide 2), a subunit of the proteasome, reduces the amount of peptide translocated into the endoplasmic reticulum and reduces levels of MHC class I on the surface of B cells.¹⁶¹⁸ Other EBV proteins and RNA including LMP1,¹⁰⁷⁴ BZLF1,^{840,957} and EBERs⁷⁸¹ up-regulate IL-10. EBV BLLF3 (dUTPase) up-regulates IL-10, as well as TNF- α , IL-1 β , IL-8, and IL-6, in resting peripheral blood mononuclear cells (PBMCs).⁴⁷⁰

EBV BARF1 is secreted from infected cells and acts as a soluble colony-stimulating factor 1 (CSF-1) receptor that blocks the activity of CSF-1.¹³⁹⁵ BARF1 inhibits IFN- α secretion from mononuclear cells.²⁵¹ EBV LF2 tegument protein interacts with IRF7, inhibiting its dimerization and reducing production of IFN- α .¹⁵⁶²

EBV BZLF1 interacts with IRF7 and inhibits its activity, which is essential for production of type I IFN.⁵¹⁸ BZLF1 also inhibits the activation of IRF7 by double-stranded RNA. BZLF1 inhibits a number of activities of IFN- γ including IFN- γ -induced MHC class II expression; activation of IRF1, CIITA, and p48; and nuclear translocation of STAT1.¹⁰⁵⁹ BZLF1 also decreases levels of IFN- γ receptor- α mRNA and levels of TNF receptor 1, which impairs TNF- α signaling.¹⁰⁵⁸

gp42 (BZLF2) binds the HLA-DR β chain and soluble gp42 inhibits antigen presentation.¹³⁸⁶ Soluble gp42 inhibits the proliferative response of PBMCs to antigen and inhibits generation of cytotoxic T cells in mixed lymphocyte cultures. gp42 binds to class II peptide complexes and sterically hinders T-cell receptor domains and inhibits MHC class II antigen presentation to T cells.¹²²⁰ gp42 is present as a type II membrane protein and as a soluble protein secreted from cells; both forms bind MHC class II and inhibit class II-restricted antigen presentation to T cells.¹²¹⁹

An EBV miRNA (miR-BART2-5P) reduces expression of MICB, a stress-induced NK-cell ligand; cells expressing miR-BART3-5P showed reduced killing by NK cells.¹⁰⁷² EBV LMP1 up-regulates expression of miR-146a, which is expressed at high levels in EBV type 3 but not type 1 latency.¹⁶⁵ miR-146a inhibits expression of IFN-responsive genes.

Several EBV gene products inhibit apoptosis. EBV BHRF1 is a homolog of bcl-2 and blocks apoptosis.⁵⁵⁷ BHRF1 blocks apoptosis by binding to Bim, a proapoptotic bcl-2 protein,³⁰⁰ as well as to Bid and PUMA.⁸²⁰ LMP1 up-regulates expression of bcl-2, which blocks apoptosis, and A20, a negative regulator of NF- κ B.⁸¹¹ The EBERs induce resistance to IFN- α -mediated apoptosis, although the mechanism by which this occurs is controversial.^{1076,1251}

EPIDEMIOLOGY

Over 90% of adults are infected with EBV. Infection is most common between the ages of 2 and 4 years and at around age 15 years.¹⁰⁸⁸ Primary infection with EBV in infants and young children is usually symptomatic or results in nonspecific symptoms. In developing countries infants and young children are infected with EBV and infectious mononucleosis is much less common. For example, in areas of Africa where Burkitt lymphoma is common, 50% of children are infected with EBV before 1 year of age. In contrast, in developed countries, about 50% of adolescents and young adults are EBV seronegative, and about 25% of these seronegative persons who become infected with EBV develop infectious mononucleosis. In studies performed at five English colleges, Yale University, and the United States Military Academy at West Point, infectious mononucleosis occurred in 28% to 74% of seronegative students.

EBV is usually spread by infected saliva. EBV infection is increased in sexually active young adults. While this may be due to kissing with sharing of oral secretions, some observations suggest that the virus may be spread by sexual intercourse. The

risk of IM was lower in students who always used condoms, suggesting that the virus may also be transmitted by sexual intercourse,⁵⁸⁰ and the risk was higher in women than men, in sexually active persons, and in those with a higher number of sexual partners.^{270,271} In addition, detection of EBV in both male and female genital secretions^{660,1353} provides a mechanism for sexual transmission of EBV; however, the level of EBV in genital secretions is lower than in saliva.¹⁴⁴³ EBV has also been transmitted by latently infected B cells through blood transfusion and by bone marrow transplant.

EBV is classified into two types, 1 and 2, based on sequence polymorphisms in EBNA-2, -3A, -3B, and -3C. Type 1 EBV isolates are more efficient in B-cell transformation *in vitro* than type 2 isolates, although differences in EBV types have not correlated with human diseases and both types co-exist in all populations that have been studied. While type 1 strains are believed to be more common in most populations, many of these studies used outgrowth assays, which may be skewed by the higher transforming efficiency of EBV type 1 strains. Type 2 isolates are nearly equal in prevalence to type 1 isolates in New Guinea and equatorial Africa. Intertypic recombinants containing portions of type I and type II EBV strains have been reported.^{1015,1584}

EBV is further classified into strains based on sequence differences. Strain differences are generally segregated with different ethnicities (African, Southeast Asia, and Caucasian). Asymptomatic carriers have multiple strains of EBV that are often different in the blood and in the throat and change over time.^{1350,1505} Patients with IM have multiple strains of EBV in the oropharynx, plasma, and PBMCs; multiple strains have been shown to be transmitted from a carrier resulting in primary infection.¹³⁵¹ Most patients with IM showed two or more EBV strains in the blood and throat, although only one strain is usually detected using *in vitro* transformation assays.¹⁴⁵¹ Multiple EBV strains persist over time; there is a trend toward restriction of the number of EBV strains in the saliva, but not in the blood.³⁶⁶

Some persons have CTL responses to polymorphic EBV T-cell epitopes and carry two distinct strains of virus with different T-cell epitope sequences.¹³⁴ While a deletion in the carboxyl terminus of LMP1 was reported to be associated with EBV-associated malignancies, this may be due instead to geographic differences.²¹³ Six variants of LMP1 that differ in sequence have been identified; however, these proteins do not differ in their transforming or signaling properties *in vitro*.⁹⁶² The majority of LMP1-specific T-cell epitopes are highly conserved in viruses from around the world.³³⁴ Differences in EBNA-1^{514,954} and LMP1 sequences¹⁴⁵ are more likely related to differences in geographic areas than to differences in biological activities of the proteins.

PRIMARY INFECTION

Healthy Carriers

In healthy carriers in developed countries, EBV is present in about 1 to 50 per million B cells in the peripheral blood.¹⁰³⁶ These cells are classic antigen-selected resting memory B cells (IgD-, CD27+, sIg+, CD20+) and are isotype switched and somatically mutated.^{61,62,1377} In Africa, particularly in areas where malaria is endemic, EBV is present in the blood of children at higher levels, approaching those seen with infectious mononucleosis.^{1046,1099}

While transcripts for LMP2 and EBNA-1 have been detected in the blood of carriers,¹⁴⁵³ more recent studies suggest that virus-infected cells in the blood have a latency 0 phenotype and express no viral genes with the exception of the EBERs.⁶⁰ The EBV viral load varies among individuals but is relatively constant at a set point within a single individual, both in healthy persons and in those with HIV.^{1036,1168} All EBV-infected persons shed virus into the saliva, although the levels vary considerably.⁹⁰⁰

In the tonsils EBV-infected CD10+ B cells are present at about three to four cells per germinal center.¹²⁴⁴ EBV-infected memory B cells in the tonsils are IgD[−] and express a type 2 latency phenotype.^{61,62} EBV-infected B cells are present at similar levels in the tonsils, adenoids, and peripheral blood, but at 20-fold lower levels in the spleen and the mesenteric lymph nodes, indicating that the subtype of memory B cells or their environment influences infection.⁸²³ EBV gene expression is similar in the spleen and tonsil (latency 2), unlike that of the peripheral blood (latency 0). When B cells in the tonsils differentiate into plasma cells, the EBV BZLF1 promoter is activated and viral replication initiates.⁸²⁴

While the EBV viral load is similar in the peripheral blood and the bone marrow, there is a threefold higher number of EBV lytic antigen-specific T cells in the bone marrow compared with the blood, although the numbers of latent antigen-specific T cells are similar at both sites.¹¹²⁸

Infectious Mononucleosis

The incubation period for IM is about 4 to 6 weeks. IM presents with fever, lymphadenopathy, and pharyngitis in more than half of patients.²⁴⁵ Posterior cervical lymphadenopathy and a tonsillar exudate are common. Other signs and symptoms include splenomegaly, hepatomegaly, rash, periorbital edema, and fatigue. Rarely EBV-positive genital ulcers can occur. Serious complications include upper airway obstruction due to enlarged tonsils, aplastic anemia, severe thrombocytopenia, granulocytopenia, autoimmune hemolytic anemia, hemophagocytic syndrome, hepatitis, jaundice, myocarditis, splenic rupture, encephalitis, meningitis, and Guillain-Barre syndrome. Most patients with encephalitis do not present with IM. While most patients' symptoms resolve in 2 to 4 weeks, up to 10% will have fatigue persisting for 6 months or more. Patients with symptoms that persist for 6 or more months do not have higher EBV DNA levels or differences in immune responses to the virus.¹⁶³

The peripheral blood shows leukocytosis, an increase in T cells but not B cells, and atypical lymphocytes. These latter cells have large amounts of cytoplasm often with vacuoles (Fig. 61.18) and are predominantly activated T cells (HLA-DR⁺), but also include NK cells. There is an increase in CD8 T cells and a decrease in CD4 T cells. T cells from patients with IM have reduced responses to mitogens *in vitro*. Pathology of lymph nodes and tonsils shows reactive follicles with proliferation of immunoblasts with reactive T cells; binuclear immunoblasts that resemble Reed-Sternberg cells are often present, which can confuse the diagnosis of IM with B-cell lymphoma. Polyclonal B-cell activation results in elevated levels of immunoglobulins, production of heterophile antibody (see Diagnosis later), and in some cases antinuclear antibodies, cold agglutinins, rheumatoid factor, or antiplatelet antibodies. Tissues have elevated levels of IL-1 β , IL-6, IL-10, TNF- α , lymphotoxin, and IFN- γ -induced chemokines (MIG, IP10).^{412,1322} The serum shows elevated levels of liver enzymes including serum transaminases and alkaline

FIGURE 61.18. Atypical lymphocytes with prominent cytoplasm and vacuoles. (From Cohen JL. Epstein-Barr virus. In: Young NS, Gerson SL, High KA, eds. *Clinical Hematology* Philadelphia: Elsevier, 2006:956–966, copyright © 2006 Elsevier.)

phosphatase. Symptoms of IM are due to the large expansion of CD8 T cells and the cytokines they produce (IL-6, IL-10, IL-12, IFN- γ , TNF- α , TGF- β ^{1113,1556}) rather than to lytic infection of B cells. In contrast, asymptomatic EBV infection is associated with a high level of EBV in the blood but not the large expansion of CD8 T cells, which occurs in IM.¹³⁴⁵ Therefore, the large expansion of CD8 T cells in IM that are associated with symptoms might not be required for control of virus infection. High-level persistent shedding of virus occurs for weeks to months after IM despite the high levels of CD8 T cells that recognize EBV lytic antigens.

It is uncertain why IM is a disease of adolescents and young adults. Some of the CD8 T cells that recognize EBV lytic proteins can cross-react with other proteins from pathogens previously seen by the immune system and might contribute to lymphoproliferation. Two patients with IM had CD8 T cells that recognized EBV BMLF1 and cross-reacted with the influenza M1 protein and accounted for one-third of the cells that recognized BMLF1.²⁴⁰ HLA MHC class I polymorphisms in HLA-A01 correlate with development of IM, severity of symptoms, and viral load in persons with primary EBV infection.⁹⁹⁷ HLA-DR polymorphisms also correlated with development of IM.¹²⁰⁶ Lymphoblastoid cell lines obtained from HLA-A01 individuals also fail to present latent EBV peptides.¹³⁰ Persons with certain polymorphisms in IL-10 have more severe disease with acute infection.^{555,556}

Patients with IM have high levels of EBV in the peripheral blood and shed high titers of virus from the throat (Fig. 61.16). Virus may be produced in lytically infected B cells⁷¹⁴ as well as in epithelial cells. The level of EBV-infected B cells in the blood drops rapidly ($t_{1/2}$ = 7.5 days) after infection, followed by a slow decline during the first year.⁵¹⁶ During the latter slow decline, the half-life of the viral load is 39 days.⁶¹² EBV levels in the peripheral blood decline during the first 6 weeks of infection and rapidly fall in the plasma during the first 2 weeks.^{71,366} High levels of virus shedding persist in the throat for prolonged periods (greater than 180 days) of time after IM. The number of infected B cells is maintained at about 1 to 50 B cells per

million after recovery.⁶¹ The half-life of EBV-specific T cells during the first 2 weeks of IM is 2.9 days.⁶¹²

From 1% to 20% of B cells in the peripheral blood are infected with EBV during IM. While up to 50% of memory B cells are latently infected with EBV, few naïve B cells are infected.⁵⁹⁷ The virus-infected cells are resting, not proliferating, memory cells (IgD–, sIg+, CD27+, CD5–, and CD20+), and while some cells have detectable transcripts for all of the latency genes,¹⁴⁵³ most do not express viral latency genes except for EBNA-1 when the cells divide.⁵⁹⁶ Viral replication in the blood is rare during IM, and nearly all the cells are latently infected. EBV-positive cells in the blood have more somatic hypermutation than EBV-negative cells.¹³⁷⁶

The frequency of regulatory T cells (CD4+, CD25^{hi}) in the blood is significantly lower in persons with IM than in seropositive blood bank donors; however, a similar frequency of regulatory T cells was observed in the tonsils of patients with IM and controls.¹⁵⁴⁷

B cells in tonsils from persons with IM show EBV latency 3 gene expression along with other forms of latency including type 1 and type 2 with variable expression of LMP1.⁸¹⁷ EBV-infected memory B cells and B cells in the germinal center of lymph nodes expand in the absence of somatic hypermutation.⁸¹⁶

EBV-ASSOCIATED DISEASES

X-linked Lymphoproliferative Disease

Patients with X-linked lymphoproliferative disease (XLP) type 1 (XLP-1) present with hemophagocytic syndrome (32% of cases), dysgammaglobulinemia (22%), a family history of XLP-1 (17%), lymphoma (14%), fulminant IM (8%), or other symptoms.¹²⁰ Acute infection with EBV usually results in a fulminant infection with organs infiltrated by proliferating B and T cells; hemophagocytic lymphohistiocytosis (HLH), bone

marrow failure with lymphocytopenia, and hepatic failure often occur.¹³¹⁵ Other patients have aplastic anemia, lymphomatoid granulomatosis, or vasculitis. Patients have an excessive T helper cell 1 (Th1) response with elevation of IFN- γ levels and large numbers of activated T cells and NK cells in the blood. Survivors of acute EBV infection often have low levels of IgG and high levels of IgM and IgA; about 20% subsequently develop B-cell lymphomas. Some patients with mutations in SAP that have not been infected with EBV develop B-cell lymphomas, vasculitis, or hypogammaglobulinemia. These patients do not have more severe infections with other viruses. Patients with XLP-1 have reduced IgG responses to vaccines, reduced IL-10 production in T cells,⁹⁴⁸ and absent NK T cells.^{1087,1141} SAP knockout mice have impaired B-cell memory.²⁷³

XLP-1 is due to a mutation in SAP (SLAM-associated protein) also known as SH2D1A^{242,1086,1291} (Fig. 61.19). SAP is an adapter protein containing a single SH2 domain. SAP is expressed in T, NK, NK T, and some B cells and interacts with SLAM on T, B, and dendritic cells.¹⁷⁰ This interaction inhibits production of IFN- γ , which is normally induced by T-cell activation. The interaction of SAP with SLAM may result in reduced IFN- γ production either by (a) impairment of SLAM binding to SHIP¹²⁹¹ or (b) recruitment of FynT, SHIP, Dok1, and Dok2 with activation of Ras-guanosine triphosphatase (GTPase)-activating protein.⁸³² SAP also interacts with other members of the SLAM family.¹⁷⁰ These include 2B4 and NTB-A, which mediate NK-cell killing; and interaction with Ly9 and CD84. The interaction of SAP with 2B4 results in recruitment of FynT, SHIP, and Vav-1, which results in increased NK-cell cytotoxicity. Impaired SAP interactions with SLAM, 2B4, and NTB-A may reduce CD8³³² and NK-cell^{123,1139} killing of EBV-infected B cells and result in excessive production of IFN- γ , which can contribute to uncontrolled T-cell proliferation and HLH. SAP also has pro-apoptotic activity and promotes reactivation-induced cell death, which is important for T-cell homeostasis.^{869,1073,1368}

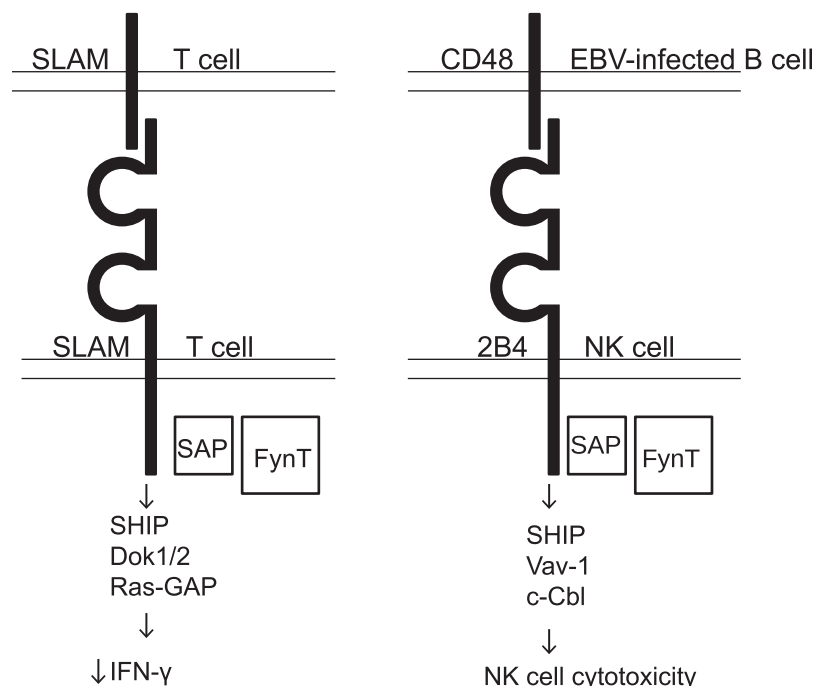

FIGURE 61.19. Interaction of SAP with SLAM and 2B4. SAP binds to SLAM on T cells and initiates a cascade resulting in decreased interferon- γ (IFN- γ). SAP binds to 2B4 on natural killer (NK) cells, which results in increased NK-cell cytotoxicity.

T cells from patients with XLP-1 are resistant to apoptosis mediated by T-cell receptor stimulation, which may contribute to the massive lymphoproliferative disease with the disease.

Patients with XLP-1 who survive infection with EBV have quantitatively normal EBV-specific CD8 T-cell responses, but their T cells are impaired for recognition of SLAM ligand-positive (but not SLAM-negative) EBV-infected B cells.⁵⁸⁸ Patients with XLP-1 lack IgD[−] CD27⁺ class-switched memory B cells, and those who survive carry EBV in nonswitched memory cells (IgM⁺, IgD⁺, CD27⁺).^{190,949} Patients with other family members with XLP-1 nearly always have mutations in SAP, whereas sporadic cases are less likely to have mutations. CD4 T cells from patients with XLP-1 do not provide optimal B-cell help, efficiently differentiate into IL-10–positive effector cells, or efficiently up-regulate inducible co-stimulator (ICOS), a potent inducer of IL-10. Adoptive transfer experiments in mice lacking SAP show that the animals have normal B cells but defective CD4 T cells.²⁷³ This results in markedly reduced numbers of virus-specific long-lived plasma cells and memory B cells with impaired long-term antibody responses, but normal or increased levels of virus-specific memory CD4 T cells. Mice²⁷⁴ and humans⁹⁴⁹ lacking SAP have markedly reduced germinal center B cells; germinal center responses require early and sustained interactions between B and T cells and SAP is essential for these interactions.¹⁶⁹ SAP expression in T cells, but not B cells, is required for normal antibody production and formation of germinal centers.¹⁴⁹³

Intravenous immunoglobulin has been used to prevent EBV infection in boys with mutations in SAP; fatal breakthroughs have occurred. While antiviral therapy and cytotoxic chemotherapy have not been successful, rituximab (anti-CD20 monoclonal antibody) has been reported to be life-saving in several patients with XLP-1 and fulminant IM.¹⁰³¹ Hematopoietic stem cell transplantation (HSCT) cures the disease and survival rates of 80% have been reported with good immune reconstitution.¹²⁰ Patients with active HLH have a lower rate (50%) of survival. Patients who are not transplanted are usually given intravenous immunoglobulin and the survival rate is 63%.

Patients with mutations in X-linked inhibitor of apoptosis (XIAP, also termed BIRC4) have many features of XLP, and this disease is referred to as XLP-2.¹²²⁵ These patients often present with HLH, recurrent splenomegaly, fever, and cytopenia. The disease is usually triggered by primary infection with EBV. XLP-2 is usually less severe than XLP-1. HLH is more common with XLP-2 than XLP-1, while hypogammaglobulinemia and low NK T-cell numbers are more common in XLP-1.^{389,1126} The high incidence of HLH and the lack of lymphomas in patients with XLP-2 have caused some authors to reconsider its classification as a form of X-linked familial HLH rather than XLP-2.⁹⁷⁸ Lymphocytes from patients deficient in XIAP have increased apoptosis in response to Fas and the TRAIL receptor.¹²²⁵ HSCT is recommended for XLP-2.³⁸⁹

Two sisters with mutations in IL-2–inducible T-cell kinase (ITK) died with uncontrolled lymphoproliferative disease after infection with EBV.⁶²⁷ NK T cells were absent from the one patient tested and high levels of eomesodermin in CD8 T cells were present in both children.

Chronic Active EBV and Related Disorders

CAEBV disease, also referred to as EBV-positive lymphoproliferative disorder of childhood, is a rare disease more common

in Asia and natives of Mexico and Central and South America. Patients present with IM-like symptoms with fever, lymphadenopathy, and hepatosplenomegaly and develop lymphoproliferative disease involving the liver, lungs, nervous system, or other organs.^{249,767,768,1118} HLH is common with fever and pancytopenia. Asian patients may have hypersensitivity to mosquito bites. The disease often presents after primary EBV infection, and patients have high viral loads and/or extremely high antibody titers to EBV VCA and EA, and infiltration of tissues with EBV-positive T, NK, or much less commonly B cells.⁷⁶⁵ Many patients have absent antibody to EBNA-1. In Japanese patients with CAEBV, EBV is often clonal in T or NK cells, while in the United States the virus is often in B cells.²⁴⁹ Patients with CAEBV have dysregulation of cytokines and often have elevations in both Th1 and Th2 cytokines.¹¹¹⁶ Patients often have low levels of EBV-specific CD8 T cells, implying a failure to control infection.¹⁴⁰³ One patient has been described who had mutations in both alleles of perforin⁷¹⁹ and another patient had a mutation in a magnesium transporter protein (MagT1),⁸⁷¹ but the etiology of the disease in other patients is not known. Patients with EBV in T cells have a poorer prognosis and often have high fever and higher EBV antibody titers to VCA and EA than those with virus in NK cells, while patients with EBV in NK cells often have hypersensitivity to mosquito bites, high IgE, and large granular lymphocytes in the blood.⁷⁶⁶ If untreated, most patients die from hepatic failure, refractory T- or NK-cell lymphomas, or opportunistic infections due to a progressive loss of immune cell function. EBV latency 2 gene expression is present in the peripheral blood of patients with CAEBV.⁶⁶⁴ While a number of therapies, including antiviral agents, immunosuppressive agents, cytotoxic chemotherapy, and autologous EBV-specific CTLs have been tried, only hematopoietic stem cell transplantation (HSCT) has been curative.⁴⁷⁸

Hydroa vacciniforme-like lymphoma is associated with CAEBV and is more common in Asians and natives of Central and South America. EBV-positive T-cell hydroa vacciniforme presents on sun-exposed areas of the skin with papules and vesicles on the face.⁶⁶⁵ EBV-positive NK-cell disease often presents with hypersensitivity to mosquito bites and patients may develop HLH. EBV-positive cells are usually clonal and have EBV latency 1 gene expression. The disease is indolent and can regress spontaneously; some cases progress with systemic symptoms with lymphadenopathy and hepatosplenomegaly. High levels of EBV DNA are in the blood. A milder form of hydroa vacciniforme presents in children or young adults with persistent papules and vesicles on sun-exposed areas, especially the face, which ulcerate. EBV is present in T cells in the lesions and the prognosis is good.

Hemophagocytic lymphohistiocytosis (HLH) is associated with CAEBV as well as with certain infections, including primary infection with EBV.⁶⁵⁴ Patients present with HLH and fever and often develop bone marrow and liver failure. The condition is frequently, but not always, seen in patients with CAEBV disease and is more common in Asians. Patients have elevated serum levels of TNF- α , IFN- γ , IL-1, sTNF-R1, and cytochrome c.⁷²⁵ Infection of T cells *in vitro* with EBV results in up-regulation of TNF- α and IFN- γ , which activates macrophages and may drive HLH.⁸³⁹ Elevated levels of IFN- γ , macrophage inflammatory protein-1 α (MIP-1 α), MIG, and IP10 are present in tissues.¹⁴⁴¹ EBV infects circulating T cells, CD5 is down-regulated on CD8 T cells, and increased HLA-DR-positive cells are observed.¹⁴⁵⁸

Adults with EBV-associated HLH have high numbers of EBV genomes in circulating NK cells.⁴¹⁵ While an elevated EBV DNA load correlates with a poorer prognosis, IgH or TCR rearrangements are not associated with a worse outcome.¹¹ In patients who do not respond to conservative measures, EBV-associated HLH is often treated using the HLH 2004 protocol with corticosteroids or cyclosporine and etoposide to control HLH.⁶⁵⁵ In most cases etoposide is not required.¹³³⁸ Patients with persistent disease or elevated viral loads are usually treated with HSCT.¹¹¹⁵

EBV Lymphoproliferative Disease: Congenital, Iatrogenic, and Posttransplant

Patients with congenital (e.g., severe combined immunodeficiency, Wiskott-Aldrich syndrome, ataxia telangiectasia), acquired (HIV), or iatrogenic (methotrexate therapy) T-cell immunodeficiencies often have elevated EBV DNA levels in the peripheral blood and throat and are at risk for EBV lymphoproliferative disease and lymphoma (Table 61.4). The underlying defect in these patients is impaired T-cell function and inability to control EBV-infected B cells. Pathology ranges

from polymorphic lymphoproliferative disease to diffuse large B-cell lymphoma.

Patients with rheumatoid arthritis or polymyositis who receive methotrexate may develop EBV lymphoproliferative disease that often resolves when methotrexate is discontinued.^{1269,1037} In this case methotrexate may increase the risk of virus reactivation as well as impair T-cell function.³⁸⁴ Patients receiving TNF- α inhibitors for rheumatoid arthritis have also developed EBV lymphoproliferative disease⁹⁷⁵; some cases resolved after stopping the drug.

EBV posttransplant lymphoproliferative disease (PTLD) occurs in 1% of kidney transplant recipients, 1% to 2% of liver transplant recipients, 1% to 3% of heart transplant patients, 2% to 5% of lung transplant recipients, and 20% of small intestine transplant patients. Bone marrow transplant recipients have a 1% incidence of PTLD, which increases in those who receive T-cell-depleted marrow or HLA-mismatched marrow. The risk of EBV PTLD is increased in persons who have a primary EBV infection, graft-versus-host disease, cytomegalovirus infection, or who receive second transplants or anti-T-cell antibodies.^{831,1504} Certain immunosuppressive

TABLE 61.4 EBV-Associated Malignancies in Immunocompromised Persons

Disease	EBV frequency	EBV gene expression	EBV latency	Genetic mutations	Cell of origin	Latency period after EBV infection	Comments
Lymphoproliferative disease in immune deficiency	100%	EBNA-1, -2, -3, -LP; LMP1, 2	3		B cell, GC, or post-GC	<3 months	Reduced T-cell immunity
Posttransplant lymphoproliferative disease	Early: <1 year after transplant >90%; late: EBV less common	EBNA-1, -2, -3, -LP; LMP1, 2	3	Early: none; late: bcl-6 +/- ras, p53, c-myc	B cell, GC, or post-GC	Early: <1 year; late: >1 year	Reduced T-cell immunity
HIV malignancies							
Burkitt lymphoma	30%–70%	EBNA-1	1	c-myc, bcl-6, +/- p53	B cell, GC	Early in HIV	35% of HIV lymphomas
Hodgkin lymphoma	>95%	EBNA-1, LMP1, LMP2	2		B cell, post-GC	Early in HIV	5% of HIV lymphomas
DLBCL—centroblast	30%	EBNA-1	1	+/- bcl-6	B cell, GC	Early in HIV	25% of HIV lymphomas
DLBCL—immunoblastic	>90%	EBNA-1, -2, -3, -LP; LMP1, 2	3		B cell, GC, or post-GC	Late in HIV	15% of HIV lymphomas, low CD4 cell numbers
Primary CNS lymphoma	>95%	EBNA-1, -2, -3, -LP; LMP1, 2	3		B cell, GC, or post-GC	Late in HIV	Low CD4 cell numbers
Primary effusion lymphoma	>90%	EBNA-1, +/- LMP1, LMP2	1 or 2	bcl-6	B cell, GC, or post-GC	Late in HIV	HIV lymphomas HHV-8+
Plasmablastic lymphoma	50%–80%	EBNA-1	1		B cell, post-GC	Late in HIV	Very rare; CD20-
Smooth muscle tumors	>95%	EBNA-2, +/- LMP1	?		Smooth muscle cell	Late in HIV	Rare

EBV, Epstein-Barr virus; EBNA, Epstein-Barr virus nuclear antigen; GC, germinal center; LMP, latent membrane protein; DLBCL, diffuse large B-cell lymphoma; CNS, central nervous system.

drugs, including tacrolimus and IL-2 receptor antagonists, are associated with an increased risk of disease; other immunosuppressive drugs such as alemtuzumab are associated with a high viral load but a low risk of PTLD.¹⁷⁷ The rate of EBV PTLD varies depending on the transplant, with higher rates associated with increasing immunosuppression.

Patients with PTLD often have elevated levels of IL-6, a B-cell growth factor, in the peripheral blood.¹⁴⁶⁹ Transplant recipients with a polymorphism in the TNF- α promoter and the TNF receptor I promoter are at increased risk for PTLD.⁹⁹⁶ Increased levels of TNF- α are also seen in the plasma of patients with PTLD. Polymorphisms in Nramp⁷⁶ and in IFN- γ ⁸⁵³ are predictive for development of PTLD in liver transplant recipients. Polymorphisms in IL-10 and TGF- β are more frequent in solid organ transplant patients with PTLD.⁶³ Transplant recipients with elevated antibody to EBV early antigens were at increased risk of developing EBV PTLD after transplant¹⁰ in one study, but not another.¹⁷⁸ Patients with EBV PTLD had a significantly higher frequency of an HLA B51 allele than transplant patients without the allele.⁴⁷⁶ HLA-B18 and HLA-B21 were associated with a higher risk of developing PTLD, while HLA-A03 and HLA-DR7 were associated with a lower risk.¹³⁹⁸

About 55% of patients (especially early after transplant) present with an IM-like illness with fever, enlargement of tonsils and adenoids, and lymphadenopathy; biopsies show plasmacytic hyperplasia and lesions are polyclonal or oligoclonal. About 30% of patients have polymorphic PTLD with monoclonal or oligoclonal lesions (Fig. 61.20). About 15% of patients have monomorphic PTLD with monoclonal disease, which includes diffuse large cell lymphoma, Burkitt lymphoma, classical

Hodgkin lymphoma-like PTLD, and plasma cell myeloma. Distinct EBV-positive clones can arise at one or more sites. In contrast, T-cell lymphomas after transplant are rarely EBV positive. The polyclonal and polymorphic PTLD lesions that occur during the first year after transplant are almost always EBV positive and have a type 3 pattern of latency. In contrast, the later monomorphic lesions are often, but not always, EBV positive and may have different patterns of latency with variable expression of EBNA-2 and LMP1. Early plasmacytic hyperplastic or polymorphic PTLD lesions usually do not have chromosomal abnormalities,¹⁷² providing further evidence that these tumors are driven by EBV. In contrast, monomorphic PTLD lesions that occur later after transplant that are centroblastic diffuse large B-cell lymphomas may have mutations in *bcl-6*.^{172,186} Monomorphic lesions may also have mutations in *p53*, *N-ras*, and *c-myc*.⁷⁹¹ Unlike many Burkitt lymphoma cell lines, which have *c-myc* translocations and often do not require EBV for survival, cells from PTLD patients require EBV to inhibit apoptosis and to drive the cells out of the G1/G0 phase of the cell cycle.¹⁴⁹⁴

PTLD may involve the lymph nodes, but lesions are often extranodal and present in the gastrointestinal tract, liver, lungs, kidney, or central nervous system (CNS). In organ transplant recipients the lesions are often in the transplanted organ, probably due to antigenic stimulation with production of cytokines and B-cell growth factors. Tumors are usually of donor origin in bone marrow transplant recipients and of recipient origin in solid organ transplant recipients. EBV-positive Hodgkin lymphoma can also occur after transplant, and in a large series all of these tumors occurred in persons who were EBV seronegative prior to transplant.¹¹⁹⁵

FIGURE 61.20. Biopsy from a patient with polymorphic (A) or monomorphic (B) posttransplant lymphoproliferative disease. (Courtesy of Dr. Elaine Jaffe.)

Sequencing of immunoglobulin heavy chain (IgH) genes from PTLD lesions show that some (especially early after transplant) have germline IgH sequences indicative of naïve B cells, while others have IgH somatic mutations that arise from antigen-selected memory B cells; in contrast, others (usually late after transplant) have mutated IgH genes (lacking a functional B-cell receptor) that are often not compatible with B-cell survival but more commonly seen with Hodgkin lymphoma.^{128,172,1454}

In immunosuppressed solid organ transplant recipients, elevated viral loads in half of the patients are due to increased numbers of cells with type 0 EBV latency in the blood, while the other patients had both type 0 latency and lytically infected cells in the blood.⁶⁰ Peripheral blood cells from solid organ transplant recipients expressed EBERs, BARTs, and LMP2, but not other latency genes.⁴⁷⁷ In a larger study of heart transplant patients with high EBV loads,⁶⁰⁶ blood from 53% of patients expressed LMP2, 25% expressed gp350, 17% expressed EBNA-3C, and 11% expressed LMP1. In another study of organ transplant recipients, 85% of those with high viral loads had LMP1 and LMP2 expression in the peripheral blood, and 20% had EBNA-1, EBNA-2, or BZLF1 expression in the blood.¹¹⁹⁴ In other studies, solid organ transplant recipients with elevated viral loads had high EBV copy numbers in cells¹²³⁹ and EBV in cells lacking surface immunoglobulin.¹²⁹⁶ PTLD biopsies

overexpress galectin-1, which tolerizes dendritic cells and induces apoptosis of cytotoxic T cells; neutralizing antibody to galectin-1 inhibited galectin-1–induced apoptosis of virus-specific CD8 T cells.¹¹²³

Detection of elevated levels of viral DNA in the blood or cerebrospinal fluid may provide a clue to the diagnosis of PTLD and also may be useful for follow-up after treatment.^{480,505} In general, very high levels of EBV DNA in the blood are predictive of PTLD, while low levels are common and often resolve without therapy.¹ Detection of EBV DNA in the plasma is more predictive of PTLD than detection in whole blood.⁷⁷¹ Patients at risk for EBV PTLD have lower levels of EBV-specific CD8 T cells in the blood,¹⁰⁰⁷ and combined viral load measurements and EBV-specific T cells may be more predictive of PTLD than either alone.^{39,1007,1363} Staging of the extent of disease is performed with computed tomography and positron emission tomography (PET) scans. Diagnosis of EBV PTLD requires demonstration of EBV and appropriate histopathology in tissue biopsies. Biopsies of PTLD lesions usually show type 3 EBV latency.¹⁶⁰⁶

Burkitt Lymphoma

Endemic BL is usually an EBV-positive tumor that occurs in equatorial Africa and New Guinea, where *Plasmodium falciparum* malaria is also endemic (Table 61.5). The disease occurs

TABLE 61.5 EBV-Associated Malignancies in Nonimmunocompromised Persons

Disease	EBV frequency	EBV gene expression	EBV latency	Genetic mutations	Cell of origin	Latency period after EBV infection
Burkitt lymphoma	Endemic 95%–100%; sporadic 15%–85%	EBNA-1	1	<i>c-myc</i> , +/– <i>p53</i> , <i>RB2</i>	B-cell GC centroblast	3–8 years
Hodgkin lymphoma	MC, LD 60%–80%; NS 20%–40%	EBNA-1, LMP1, LMP2	2		B-cell post-GC	1 year or more
Nasopharyngeal carcinoma	Anaplastic 100%; keratinizing 30%–100%	EBNA-1, LMP2, +/–LMP1	2	Various tumor suppressor genes	Undifferentiated epithelial cell	>30 years
Gastric carcinoma	Lymphoepithelioma 100%; adenocarcinoma 5%–15%	EBNA-1	1		Gastric epithelial cell	>30 years
Diffuse large B-cell lymphoma of the elderly	Up to 25%	EBNA-1, LMP1,2 +/–EBNA-2	2 or 3		B cell, GC, or post-GC	>30 years
Peripheral T-cell lymphoma associated with CAEBV or acute EBV infection	100%	EBNA-1, LMP2, +/–LMP1	2		Mature CD4+ T cell	None or several months
Angioimmunoblastic T-cell lymphoma	>90%	EBNA-1, LMP1,2	2	Trisomy 3 or 5	Lymphoma in CD4 T cells; EBV in B cells, GC	>30 years
Pyothorax lymphoma	100%	EBNA-1, 2, +/–LMP1	3	p53	B cell, GC, or post-GC	>30 years
Extranodal NK/T nasal	100%	EBNA-1, LMP2, +/–LMP1	2		CD3–, CD56+	>30 years

EBV, Epstein-Barr virus; EBNA, Epstein-Barr virus nuclear antigen; RB2, retinoblastoma-like 2; GC, germinal center; MC, mixed cellularity; LD, lymphocyte depleted; NS, nodular sclerosis; LMP, latent membrane protein.

at 5 to 10 cases per 100,000 children and is the most common childhood tumor in these areas.³⁶⁵ Endemic BL usually presents as a tumor in the jaw. The B-cell proliferation and reduction in virus-specific cytotoxic T cells associated with malaria are thought to increase the EBV viral load and enhance the risk of chromosomal *c-myc* translocations present in BL cells.

Sporadic BL occurs in the United States and Europe at a rate of 0.2 to 0.3 cases per 100,000 persons and only 20% of tumors are EBV-positive. The disease is more common in South America and North Africa, with rates of 1 to 2 per 100,000 persons, where up to 85% of BL is EBV positive. Sporadic BL usually presents in children with abdominal tumors. About 40% of BLs in patients with AIDS are EBV positive. The disease occurs early in the course of HIV when immune function is relatively intact. HIV, like malaria, also induces B-cell proliferation and impairs EBV-specific CTL activity. Pathology of BL shows atypical B cells with basophilic, vacuolated cytoplasm and irregular nuclei with prominent nucleoli in a background of phagocytic histiocytes resulting in a “starry sky” pattern (Fig. 61.21). The lymphoid tumor cells often show mitotic figures and evidence of apoptosis.

BL cells shows dysregulation of the *c-myc* oncogene due to an 8:14, 8:2, or 8:22 chromosomal translocation in which a portion of the immunoglobulin heavy chain (on chromosome 14) or light chain (on chromosome 2 or 22) is fused to *c-myc* (on chromosome 8). Analysis of the structure of the chromosome breakpoints suggest that the *c-myc*/immunoglobulin gene translocations occur during the germinal center reaction either due to somatic hypermutation or to an error during class-

switch recombination.⁸¹⁴ Increased expression of *c-myc*, due to its proximity to the immunoglobulin enhancer sequence, affects expression of greater than 15% of genes in BL cells.⁸⁷⁹ *c-myc* reduces the immunogenicity of EBV-positive cells by inhibiting expression of TAPs, reducing expression of MHC class I, and inhibiting expression of proteasome subunits that are important for antigen presentation.¹³⁸⁸ However, impairment of proteasome function by *c-myc* may be compensated by the ability of *c-myc* to activate another pathway involving tripeptidylpeptidase II for proteolysis.⁴⁵⁰ *c-myc* can substitute for many of the growth-transforming functions of LMP1 and EBNA-2.¹¹⁷³ Expression of *c-myc* impairs NF- κ B and interferon responses in BL cells.¹³⁰⁴ Transgenic mice expressing *c-myc* driven by immunoglobulin light chain sequences develop tumors resembling BL.⁸⁰¹ Expression of *c-myc* is not compatible with expression of EBNA-2, which, if transcriptionally active, is functionally mutated.⁷³⁷ In addition, EBNA-2 down-regulates expression of *c-myc*.⁶⁹³ Therefore, high levels of *c-myc* expression limit EBV latency gene expression in BL.

Analysis of immunoglobulin gene rearrangements shows that EBV-positive endemic BLs and AIDS-related BLs have high IgH mutation rates with signs of antigen selection, while EBV-negative sporadic BLs have low mutation rates without signs of antigen selection.⁹³ This indicates that endemic and AIDS-associated EBV-positive BLs evolve from late germinal center B cells (or memory B cells), while sporadic EBV-negative BLs evolve from early centroblasts. Sequencing of immunoglobulin genes from endemic BL cells showed that multiple mutations evolve *in vivo*.¹⁹⁵ BL cells express cell surface markers present on germinal center cells with CD77 (BL antigen), CD10, bcl-6, CD38, and PAX5.¹⁴⁴⁴ Unlike lymphoblastoid cells, BL cells do not express adhesion molecules (e.g., LFA-1, ICAM1), B-cell activation antigens (e.g., CD23, CD70), co-stimulatory molecules (e.g., CD80, CD86), or bcl-2. Gene expression profiling confirms that BL cells have high-level expression of *c-myc*, expression of a subset of germinal center genes, and low-level expression of MHC class I genes.²⁸⁷ Low-level expression of MHC class I and TAPs in BL cells reduces recognition by class I-restricted CTLs; however, BL cells do express MHC class II.⁷⁵⁵

EBV endemic BL contains clonal viral genomes and usually has a type I EBV latency pattern in tissues and *in vitro*. The cells express EBNA-1 driven by the Qp promoter and grow as single cells *in vitro*. EBNA-1 expression is critical for survival of BL cells; inhibition of EBNA-1 induces apoptosis and reduces survival of EBV-positive BL cells.⁷⁴² More sensitive assays indicate that some BL cells express LMP2.⁹¹ Some endemic BL cells express EBNA-1, EBNA-3A, EBNA-3B, EBNA-3C, a truncated EBNA-LP, and low-level LMP2, but not LMP1, and there is a deletion in EBNA-2.⁷³⁷ These grow as single cells *in vitro* and use the Wp promoter for expression of EBNAs. Rare BLs have been reported with cells containing different patterns of EBV latency that may enhance the ability of the tumor to escape apoptosis.⁷³⁹ Other BL cells, especially those resistant to apoptosis, express EBV BHRF1, a bcl-2 homolog.⁷³⁸ Transcriptional profiling of type I EBV latency BL cell lines showed expression of lytic genes, especially BHRF1 and LF3 at high levels.⁸⁹⁵ While some EBV BL cells lose their EBV genome during passage *in vitro*,¹³³⁵ this has not been observed *in vivo*, indicating that the EBV genome has an important role in maintaining the tumor even with limited viral gene expression.

FIGURE 61.21. Biopsy from a patient with Burkitt lymphoma. The intensely stained B cells in a background of lightly stained histiocytes give a “starry sky” appearance. (Courtesy of Dr. Elaine Jaffe.)

In addition, BL cells that lost their EBV genomes *in vitro* had a less malignant phenotype with reduced tumorigenicity in mice. While some studies have postulated that the EBERs are primarily responsible for EBV's contribution to the malignant phenotype in some BL cells,⁷⁹⁵ this has not been observed in other BL cells.⁹⁸⁷

With increasing passage in cell culture, some BL cell lines switch from a latency 1 to a latency 3 pattern of EBV expression and the EBNAs are driven by the Cp or Wp promoters.^{1249,1272} These cells grow in clumps and express adhesion molecules (ICAM1, LFA3), B-cell activation markers (CD23, CD70), co-stimulatory molecules (e.g., CD80, CD86), and bcl-2. These latter cells express lower levels of c-myc. Cells that use the EBV Wp promoter require EBV to inhibit apoptosis induced by Bim and to proliferate efficiently.¹⁴⁹⁴

EBV-positive endemic BL has fewer secondary genomic alterations than EBV-negative sporadic BLs.⁷⁸ However, EBV infection of virus-negative BL cells results in chromosome instability; while this effect is seen in BL cells with EBV latency 1 gene expression, it is more prominent in BL cells with latency 3 gene expression.⁷⁰⁵

Children in Africa with increased antibody titers to EBV VCA are at increased risk of BL.³⁰³ Patients with endemic BL often have elevated antibody titers to EBV VCA as well as EA-R. Elevated serum antibody titers to EBV lytic and latent proteins were observed in children in areas where malaria was holoendemic and the levels remained elevated, while antibody titers were lower and declined in persons from areas where malaria was sporadic.¹¹⁶⁶ Children with BL in Malawi had higher levels of antibodies to EBV and malaria and were more likely to be HIV positive.¹⁰⁷¹ Children in Gambia with malaria had higher EBV viral loads than those without malaria and had evidence of impaired EBV-specific CD8 T cells during onset of malaria.¹⁰⁹⁹ Children with BL in Africa where malaria is holoendemic were less likely to have EBNA-1-specific IFN- γ responses compared with healthy children in the same area, while CD8 T-cell responses to other latent and lytic antigens were similar in children with endemic BL and controls.¹⁰⁴⁸ Children aged 5 to 9 years old who lived in an area holoendemic for malaria had lower EBV-specific IFN- γ responses than those in a non-holoendemic area; this coincided with the peak age incidence of endemic BL in this area.¹⁰⁴⁷ This effect was not seen in children younger than 5 or older than 9 years old. Children living in areas of Africa where malaria is holoendemic had higher EBV DNA loads than those in areas where the disease was sporadic, and viral loads were highest in very young children.¹⁰⁴⁶ Children in South America, where Burkitt lymphoma is sporadic, had high levels of EBV DNA in the blood at the time of diagnosis.⁹⁵¹ Antimalarial therapy resulted in a decline in the EBV viral load in the blood 2 weeks after treatment, but not in the saliva.³²³ A domain in the *P. falciparum* membrane protein 1 is a polyclonal B-cell activator, and incubation of this protein domain with PBMCs increases the EBV DNA copy number.²¹⁴ This suggests that chronic exposure to malaria may promote B-cell proliferation and BL.

Hodgkin Lymphoma

Classical Hodgkin lymphoma (HL) consists of four histologic subtypes: in the United States and Europe 75% to 80% of classical HL is the nodular sclerosis subtype, 15% to 20% is the mixed cellularity subtype, 5% is the lymphocyte-rich subtype,

FIGURE 61.22. Biopsy from a patient with Hodgkin lymphoma, mixed cellularity. The large binucleate cell in the center is a Reed-Sternberg cell. (Courtesy of Dr. Elaine Jaffe.)

and less than 1% is lymphocyte depleted. The frequency of EBV positivity is 80% to 90% for lymphocyte depleted, 60% to 75% for mixed cellularity, 20% to 40% for nodular sclerosis, and less than 10% for lymphocyte rich. EBV proteins and clonal viral DNA are present in Reed-Sternberg cells (large multinucleated cells of B-cell lineage) in about 40% of cases in the United States and Europe. Reed-Sternberg cells have clonal immunoglobulin gene rearrangements and express B-cell activation antigens CD25 and CD70, although they usually do not express CD19 or CD20. Patients present with lymphadenopathy and often have involvement of the bone marrow, liver, and spleen. Pathology shows rare (less than 1%) Reed-Sternberg cells in a background of lymphocytes, granulocytes, histiocytes, and plasma cells (Fig. 61.22).

EBV-positive HL is more common than EBV-negative disease in patients in developing countries including Central and South America (80% to 90% EBV-positive) compared with affluent countries (30% to 40% EBV-positive) in some⁴⁷¹ but not all studies.¹²¹⁰ HL is more commonly EBV positive in children and older adults than in young adults.⁴⁸ HL is nearly always EBV positive in immunosuppressed patients.

Elevations in IgG antibody to EBV VCA, EBNA-2, and EA-D are present at a mean of 4 years before diagnosis of HL.¹⁰⁶⁴ Increases in each of these antibodies carries a three- to fourfold relative risk of subsequent development of HL. Patients with EBV-positive HL have detectable EBV DNA in the plasma before therapy.⁴⁴⁵ EBV DNA in the plasma declines in response to therapy and increases before disease recurs.¹³⁷⁸ The level of EBV is higher in the blood of persons with EBV-positive HL

compared with EBV-negative disease⁷⁵² and higher in patients with advanced-stage disease.⁵⁹⁹

The risk of EBV-positive HL is higher within 1 year in persons with IM and decreases to normal after 10 years.⁵⁹² There is a 2.6–⁵⁹³ to 3.4-fold^{594,595} increased risk of HL after IM. The risk is fourfold in younger adults. In these studies, HL occurred a median of 2.9 years after IM. In contrast, there was no increase in other lymphoid tumors after EBV IM,⁵⁹³ including EBV-negative HL or non-Hodgkin lymphoma.^{100,595}

Sequencing of immunoglobulin genes from HL indicates that the tumor cells have mutated immunoglobulin genes and are derived from crippled germinal center B cells.⁷¹¹ Of the reported cases of HL with crippling immunoglobulin gene mutations, about 90% of EBV-positive HLs had these mutations, while only about 40% of EBV-negative HLs had these mutations.¹²⁷ These immunoglobulin gene mutations, which result in loss of functional immunoglobulin, would be expected to be lethal for the cells; however, the presence of EBV LMP1 and LMP2A, which inhibit apoptosis by stimulating NF- κ B¹⁴⁸ and providing a B-cell growth stimulus mimicking the Ig receptor,¹⁵⁶ respectively, may allow these cells to survive. In this way EBV gene expression may substitute for host cell gene mutations in I κ B α or amplification of *REL* that also activates NF- κ B in EBV-negative HL.⁸¹⁵ EBV-infected B cells lacking surface immunoglobulin (and therefore B-cell receptor deficient) with or without inactivating mutations in IgH sequences have also been generated *in vitro* by infecting germinal center cells from tonsils with EBV.^{85,188} Therefore, EBV can rescue B-cell-receptor-deficient germinal center B cells from apoptosis so that they no longer are dependent on survival signals that uninfected B cells require.

Biopsies from EBV-positive HL have type 2 EBV latency with expression of LMP1, LMP2A, and LMP2B; EBNA-1 driven by the Q μ promoter; EBERs; and BARTs.²⁹⁶ Expression of LMP1 in germinal center B cells results in reduced expression of genes that are commonly down-regulated in HL such as CD79A, CD19, CD20, and CD22.¹⁵⁰⁰ EBNA-1 down-regulates expression of Smad2, which in turn down-regulates expression of the protein tyrosine phosphatase receptor κ , which enhances proliferation and viability of HL cells.³⁹⁸ LMP1 up-regulates Bmi-1 in HL cells, which may increase survival of these cells.³³⁷ EBV infection of HL cells induces expression of autotaxin, which increases lysophosphatidic acid and increases growth and survival of HL cells.⁸³ Autotaxin is also increased in EBV-positive HL tissue. EBV-positive HL shows higher levels of CCL20, which can induce trafficking of regulatory T cells into the tumors.⁸²

Polymorphisms in the HLA class I region associate with EBV-positive HL, while those in HLA class III correlate with EBV-negative disease.³¹² This suggests that presentation of EBV peptides to CTLs is related to the pathogenesis of HL and that ethnic variations in the disease may be related to HLA sequences. Further studies showed that patients with an HLA-A02 allele have a reduced risk of developing EBV-positive HL; conversely, those with an HLA-A*01 allele have an increased risk.^{594,1091} A polymorphism in the IL-10 promoter was more common in persons with EBV-positive HL than in EBV-negative disease.²⁷⁶ Biopsies from patients with EBV-positive, but not EBV-negative, classical HL show down-regulation of miR-96, miR-128a, and miR-128b.¹⁰⁷⁷

EBV-specific T-cell function is impaired in HL. Galectin-1, an immunomodulatory protein, was expressed in the majority of

classical HL tissues examined (and in Reed-Sternberg cell lines from HL) and expression was associated with reduced LMP1- and LMP2-specific CD8 T-cell responses and reduced CD8 T-cell infiltrates in tumor tissues.⁴⁴⁷ CD8 T cells specific for LMP1 and LMP2, but not EBNA or lytic proteins, from patients with HL have impaired function. Galectin-1 reduces degranulation and recognition of epitopes by LMP-specific T cells.¹³⁶⁴ Regulatory T cells are increased in the blood of patients with HL with active disease, compared with those in remission.⁴⁴⁶ Expression of LAG-3, which is a marker of regulatory T cells, is increased in infiltrating lymphocytes in EBV-positive HL tissue and is associated with impaired EBV LMP1- and LMP2-specific CD8 T-cell responses. Many patients with EBV-associated HL lack detectable CD4-specific T-cell responses to EBNA-1.⁵⁴⁹

EBV positivity in HL improves prognosis in children younger than 15 years of age but has a poorer prognosis in adults 45 years or older.⁷³⁵ Overall survival is higher in patients with EBV-positive HL than EBV-negative disease, independent of gender, stage of disease, and B symptoms.⁶⁷⁹

Nasopharyngeal Carcinoma

Nasopharyngeal carcinoma (NPC) is classified as keratinizing or nonkeratinizing with differentiated or anaplastic subtypes. In the United States, 63% of NPC is anaplastic, 25% keratinizing, and 12% differentiated, while in Southern China 95% of NPC is anaplastic. Anaplastic NPC is more prevalent in certain areas including Southeast Asia (especially Southern China), Northern Africa, and Eskimos in the Arctic.³⁰² In Southern China the rate of disease is 50 per 100,000 in men over 50 years old. The disease has a two- to threefold higher rate in men than women. The incidence of disease peaks at ages 50 to 59, with a smaller peak in adolescents and young adults. The rates are also elevated in Chinese persons who migrate from China. Environmental factors, especially dietary habits (use of salted fish and preserved foods), as well as genetic factors, may play a role in development of the disease. The rate of NPC has been declining in developed areas of Southeast Asia, perhaps due to changes in dietary habits. NPC occurs less commonly in the United States and Europe, with rates of 0.5 to 2 per 100,000.

Genome-wide association studies have identified multiple NPC-associated genes including γ -aminobutyric acid type B receptor 1, TNFRSF19, integrin- α 9, and loci within HLA-A.^{87,1474} A polymorphism in TLR3 was also associated with a higher risk of NPC.⁵⁴³

Virtually all anaplastic NPC is EBV positive. EBV is also present, although at a lower frequency, in more differentiated (keratinizing) forms of NPC, especially in areas where anaplastic NPC is endemic. EBV is clonal in high-grade preinvasive lesions (carcinoma *in situ* or dysplasia) as well as in NPC,¹¹⁴² but not in low-grade preinvasive lesions. Thus, the virus likely infects epithelial cells that already have a genetic abnormality. Pathology of anaplastic NPC shows uniform malignant epithelial cells with prominent nuclei in a dense background of lymphocytes (Fig. 61.23). EBV DNA is present in the transformed epithelial cells but not in the infiltrating lymphocytes. The tumors are sometimes referred to as lymphoepitheliomas. However, in contrast to many other EBV malignancies, NPC tumors have normal antigen processing and are efficiently recognized by virus-specific CTLs.⁷⁵⁶

NPC is believed to be a multistep process initially with overexpression of *p53* and loss of expression of the tumor

FIGURE 61.23. Biopsy from a patient with nasopharyngeal carcinoma. A: Undifferentiated anaplastic carcinoma. **B:** *In situ* hybridization shows Epstein-Barr virus (EBV)-encoded RNA (EBER)-positive carcinoma cells. (Courtesy of Dr. Paul A. VanderLaan.)

suppressor genes *p16* and *p27* (and in some cases increased *p21Ras*) resulting in a hyperplastic lesion. This is followed by EBV infection and increased expression of *bcl-2* resulting in a dysplastic lesion, and then overexpression of *p53* and invasive NPC (Fig. 61.24).³⁷⁷ A large number of tumor suppressor genes are hypermethylated resulting in reduced expression in NPC including *TFPI-2*,¹⁵²⁹ *DLEC1*, *BLU*, and *E-cadherin*.⁵⁸ Twist and Snail, which are repressors of E-cadherin and regulators of epithelial–mesenchymal transition, are induced by LMP1 and correlate with the metastatic behavior of NPC.⁶⁰⁸

The risk for NPC is much higher (hazard ratio 6.8) for family members (when one member has the disease) compared with others in the same community.⁶²² The risk of NPC is higher for those with elevated anti-EBV DNAase antibody or anti-EBV VCA IgA (hazard ratio 2.8) and even higher when both antibodies are elevated (adjusted hazard ratio 15.1). Persons with a family history of NPC and elevated EBV serologies had a higher risk of NPC (hazard ratio was 31) than those without a family history and negative serology for DNAase and VCA IgA.⁴²⁶ A prospective study found a 21-fold increased risk of NPC in persons with rising titers of IgA antibody to EBV VCA.¹⁷¹ Elevated levels of anti-EBV EBNA1 IgA were associated with a fivefold risk of NPC.¹⁶¹⁰

Patients with NPC usually have high titers of antibody to EBV VCA, EBNA, and EA-D IgA; unlike other EBV tumors, elevated antibodies to EBV occur in NPC regardless of the geographical location. IgA to EBV VCA or EBV DNAase in serum

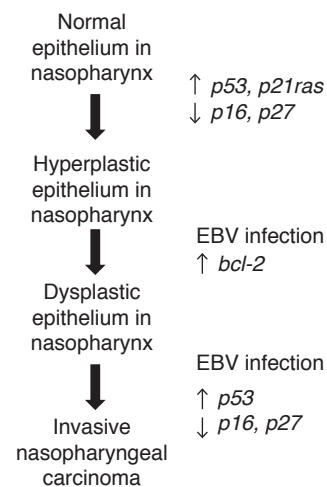

FIGURE 61.24. Steps involved in the development of nasopharyngeal carcinoma. Epstein-Barr virus (EBV) infection occurs after the cells have undergone initial genetic changes and have a hyperplastic or dysplastic phenotype. (Adapted from Fan SQ, Ma J, Zhou J, et al. Differential expression of Epstein-Barr virus-encoded RNA and several tumor-related genes in various types of nasopharyngeal epithelial lesions and nasopharyngeal carcinoma using tissue microarray analysis. *Hum Pathol* 2006;37[5]:593–605.)

or saliva has been used for screening in endemic areas.²²⁵ Persons with a fourfold increase in IgA VCA have an 18% risk of developing NPC within 3 years in China; some patients have loss of antibody and loss of risk. EBV IgA antibody levels are elevated up to 10 years before the diagnosis of NPC with a mean duration of 37 months before diagnosis.⁶⁸⁵

NPC patients often have elevated levels of EBV DNA in the plasma.⁸⁹³ The sensitivity of EBV DNA, VCA IgA antibody, and combined EBV DNA and VCA IgA for diagnosis of NPC was 95%, 81%, and 99%, respectively.⁸⁶¹ The specificity of EBV DNA and VCA IgA was 98% and 96%, respectively. Higher EBV plasma levels at the time of diagnosis and rising levels of EBV VCA or EA IgA antibody, or EBV DNA after therapy is associated with a poorer prognosis. After therapy the serum level of EBV DNA and IL-6 often declines.^{31,1424} Another noninvasive test for NPC involves brushing suspicious areas of the nasopharynx and performing polymerase chain reaction (PCR) for EBV DNA and detecting EBV DNA and RNA.¹³⁹² High levels of EBV DNA in brushings had a specificity of 98% and sensitivity of 90% for NPC. EBNA-1 and BARF1 mRNA were found in 86% and 74% of brushings, respectively, from NPC-positive patients.

Patients with NPC have lower levels of EBNA-1-specific CD8 T cells⁴⁰⁷ and lower levels of LMP1- and LMP2-specific T cells⁸⁷² than controls. Patients with NPC have lower levels of naïve CD3+CD45RA+ and CD4+CD25- cells in the blood and higher levels of activated CD4+CD25+ T cells and CD3-CD16+ NK cells than controls. EBV-specific CTL activity could be reactivated in peripheral blood mononuclear cells by incubation with autologous lymphoblastoid cell lines, while tumor-infiltrating lymphocytes from NPC biopsies lacked cytotoxic activity and did not produce IFN- γ when incubated with autologous lymphoblastoid cell lines. NPC tumors have high levels of regulatory T cells (CD4+CD25^{hi}, Foxp3).⁸³³ These cells may inhibit immune surveillance of the tumors.

NPC usually has type 2 EBV latency with EBNA-1 driven by the Qp promoter, expression of EBER and BARTs, and variable expression of LMP1; in many cases LMP1 is undetectable.⁹¹ In contrast, LMP1 is routinely expressed in preinvasive lesions.¹¹⁴² LMP2A is usually expressed in NPC biopsies, and its expression may be important for NPC, because LMP2A expression in epithelial cells increases expression of integrin- $\alpha 6$ proteins, which increases their migration and invasiveness.¹¹⁴⁷ In addition, LMP2A activates PI3K and Akt, resulting in activation of β -catenin and inhibition of differentiation of epithelial cells.¹⁰⁵⁷ Higher mutation rates in the sequence of LMP2 were seen in NPC tumors than in isolates from the oropharynx of healthy persons.¹⁵³² While BARF1¹³⁹² and BZLF1 were present in some tumor cells,²⁴¹ other lytic proteins were generally not expressed. microRNAs from BART, but not BHRF1, are expressed in NPC.^{264,914,1634} BART miRNAs interact with the 3' nonterminal region (NTR) of LMP1 and reduce its expression. This may explain the variable expression of LMP1 protein in NPC despite frequent detection of LMP1 transcripts.⁹¹⁴ BART miRNAs may also inhibit apoptosis.⁹⁷⁷ miR-218 suppresses NPC progression by down-regulating survivin.¹²

NPC cells release exosomes that contain galectin-9, which can induce apoptosis of EBV-specific CD4 T cells; galectin-9 is also present in exosomes from plasma of patients with NPC.⁷⁸⁵ Exosomes from NPC cells also contain LMP1, viral miRNAs, and signal transduction molecules, which activate signaling

FIGURE 61.25. Biopsy from a patient with lymphoepithelioma involving tonsil. The biopsy shows nodular infiltrates of undifferentiated tumor cells with macronucleoli. Lymphocytes infiltrate the tumor nodules. The tumor cells were positive for Epstein-Barr virus (EBV) by *in situ* hybridization. (Courtesy of David Kleiner.)

pathways in recipient cells.¹⁰⁰⁶ Lesions from patients with NPC often show down-regulation of TAP1, tapasin, and MHC class I, and up-regulation of IL-10.¹¹¹⁴

EBV is also present in other epithelial cell tumors (known as lymphoepitheliomas or undifferentiated carcinomas of the nasopharyngeal type) including the tonsils (Fig. 61.25), salivary glands, thymus, larynx, lungs, skin, and cervix. Like NPC, these tumors are more common in certain areas of the world, especially Southeast Asia and Eskimos in the Arctic. Also similar to NPC, pathology shows malignant EBV-positive epithelial cells with a dense infiltrate of lymphocytes. When a family member was diagnosed with NPC, the risk to other members for carcinoma of the salivary gland was 8.4 and for carcinoma of the uterine cervix was 2.2.⁴²⁶

Gastric Carcinoma

EBV is present in about 9% to 10% of gastric carcinomas including over 90% of gastric lymphoepithelioma-like carcinomas, 7% of moderately to well-differentiated gastric adenocarcinomas, and 6% of poorly differentiated gastric adenocarcinomas.^{434,652} Worldwide, gastric carcinomas may be the most common EBV-associated malignancy. The prevalence of EBV-positive gastric carcinoma is similar in the United States, Europe, and Asia.¹⁰⁶⁸ Lymphoepithelioma-like carcinomas have

a similar pathology to NPC with EBV DNA in malignant epithelial cells and a dense infiltrate of EBV-negative lymphocytes and macrophages surrounding the tumor cells.¹³³¹ EBV-positive gastric carcinomas often involve the upper third of the stomach. Meta-analyses found that the prevalence of EBV positivity in gastric carcinoma was twofold higher in men than in women, more common in younger persons, more frequent in the gastric cardia or corpus than the antrum, and more common in post-surgical gastric remnants.^{846,1068}

Gastric carcinoma cells are clonal or oligoclonal for EBV DNA. EBV-positive gastric carcinomas have an EBV type 1 latency pattern, with EBNA-1 driven by the Qp promoter, expression of EBERs and BARTs, and variable expression of LMP2A.^{434,1405} EBNA-1 expression on gastric carcinoma cells is associated with loss of PML bodies, impaired response to DNA damage, and reduced apoptosis.¹³⁵²

BARF1 is also expressed in the tumors, in the absence of other lytic genes.¹³²¹ Expression of p16, p27, E-cadherin, and p73 is reduced in EBV-positive gastric cancer, while expression of cyclin D1 and NF- κ B are increased compared with EBV-negative cancer.^{86,193} p53 and bcl-2 are overexpressed in some but not all EBV-positive gastric cancer. The tumor cells do not express CD21, the B-cell EBV receptor. DNA methylation of CpG sequences in the promoters of tumor suppressor genes such as *PTEN* is induced by LMP2 by up-regulation of *de novo* methyltransferase 1.⁴³⁴ MHC class I is down-regulated in EBV-positive gastric carcinoma cells.³³⁶ Like NPC, BART miRNAs, but not BHRF1 miRNAs, are expressed in tissues from patients with EBV-positive gastric carcinoma.⁷⁶³

EBV was not detected in preneoplastic (dysplasia and intestinal metaplasia) lesions in patients with EBV-positive gastric carcinomas, but only in the carcinomas.¹⁶⁴³ This suggests that like NPC, EBV infection is a late event in the development of gastric carcinoma. EBV gastric carcinoma is associated with atrophic gastritis and lymphocytic infiltration.

Like NPC, levels of anti-EBV VCA IgA are higher in persons who subsequently develop EBV-positive gastric carcinoma than controls.⁸⁶⁴ Levels of anti-EBV VCA IgG and anti-EA IgG antibodies are higher in patients with EBV-positive gastric carcinoma than those with EBV-negative cancer.⁶⁵² EBV anti-VCA and anti-EBNA antibodies titers are higher in persons with dysplasia on gastric biopsy, suggesting that EBV reactivation could be related to an early phase of gastric carcinoma.¹³⁰²

EBV-positive gastric carcinomas with a lymphoepithelial-like histology and large numbers of tumor-infiltrating lymphocytes generally have a better prognosis than EBV-positive carcinomas with an adenocarcinoma histology and a patchy lymphocytic infiltrate.¹³⁷² EBV-positive gastric carcinomas are less likely to spread to lymph nodes than EBV-negative tumors.

Non-Hodgkin Lymphomas and Other Malignancies in Nonimmunocompromised Persons

EBV is present in about 6% of cases of non-Hodgkin lymphoma (NHL)⁵²⁰ in Europe. This includes EBV-positive diffuse large B-cell lymphoma in the elderly, diffuse large B-cell lymphoma, peripheral T-cell lymphoma, angioimmunoblastic T-cell lymphoma, lymphomatoid granulomatosis, and pyothorax-associated lymphoma. In Asia, EBV is associated with NK/T-cell lymphoma and aggressive NK-cell leukemia/lymphoma.

miRNA expression is altered in EBV-positive versus EBV negative NHL.⁶⁵⁶

EBV positive diffuse large B-cell lymphoma of the elderly usually presents in persons older than age 60 with fever and weight loss. The disease is often extranodal and can involve the skin, stomach, and lung. Disease is thought to be due to senescence of EBV-specific T-cell responses and the proportion of EBV-positive cases increases with age.¹¹²⁵ Tumor cells are monoclonal and EBER positive, express LMP1, and have variable expression of EBNA-2. The disease has a poorer prognosis than diffuse large B-cell lymphoma.¹⁵⁵¹ About one-third of cases have an HL-like morphology with Reed-Sternberg-like cells. The disease has a poorer prognosis than classical HL in elderly persons.^{52,1336}

EBV-positive mucocutaneous ulcers are also more common in the elderly and they respond to reduction in immunosuppression or may spontaneously regress.³¹⁷

Diffuse large B-cell lymphomas are EBV positive in 10% of nonimmunosuppressed persons; the rate of EBV positivity is higher in immunocompromised persons. EBV-positive diffuse large B-cell lymphomas have a poorer prognosis than EBV-negative lymphomas and are associated with increased age, extranodal disease, fever, and a poorer response to therapy.¹¹³⁵ About 40% of CD30+ anaplastic large B-cell lymphomas are EBV positive and express LMP1 with variable expression of EBNA-2.⁸¹⁹ About 15% of large B-cell lymphomas in the oral cavity are EBV positive,¹³⁷⁰ while approximately 20% of T-cell-rich B-cell NHL is EBV positive.⁵⁷

Peripheral T-cell lymphomas usually present with fever and lymphadenopathy and are often associated with HLH.⁷⁰⁶ The disease is more common in Asians and persons from South America. Macrophage activation is often present with elevated serum levels of TNF- α , IFN- γ , and other cytokines.⁸³⁹ Elevated levels of TNF- α in the serum are associated with a poorer prognosis.¹⁰⁵⁴ Patients present either during primary EBV infection or during the course of chronic active EBV.^{698,1197} T-cell lymphomas have clonal EBV DNA and usually have type 2 EBV latency, although expression of LMP1 can be variable.²⁰⁴ The lymphoma can involve α/β or γ/δ T cells.

Angioimmunoblastic T-cell lymphoma is a peripheral T-cell lymphoma that presents with fever, night sweats, weight loss, hepatosplenomegaly, lymphadenopathy, and hypergammaglobulinemia. The malignant T cells are usually clonal and patients may develop EBV-positive diffuse large B-cell lymphoma. Autoantibodies including immune complexes, cold agglutinins, rheumatoid factor, and anti-smooth muscle antibodies may be present. EBV is present in over 90% of cases and the virus is present in the proliferating B cells that accompany the malignant T cells.¹⁵³⁷ EBV-infected B cells can be polyclonal, oligoclonal, or clonal and are deficient in immunoglobulin receptor.¹²⁹ EBV DNA is elevated in the serum and parallels the clinical course.⁵⁵

Lymphomatoid granulomatosis usually presents with fever and masses in the lungs but also can involve the kidneys, skin, liver, and central nervous system. Many patients with lymphomatoid granulomatosis have reduced numbers of CD8 and CD4 T cells; some patients have HIV or XLP1 or have received organ transplants.⁶⁷⁴ Pathology shows EBV in rare B cells, an exuberant T-cell response, and destruction of small blood vessels. Separate clonal lesions can arise at different sites. Lesions express EBV EBNA-2 and LMP1,¹⁴²⁶ and EBV DNA levels in the blood are usually not elevated. IFN- α is often effective in early-stage disease, while late-stage disease requires cytotoxic chemotherapy.

Pyothorax-associated lymphoma is an EBV-positive diffuse large B-cell lymphoma that originates in the pleural cavity after a history of pyothorax. Tumors usually express EBNA-1, EBNA-2, and/or LMP1.⁴⁰ The disease is probably due to chronic inflammation, persistent cytokine production, and reduced host immunosurveillance. Similar localized EBV-positive lymphomas, termed *diffuse large B-cell lymphoma associated with chronic inflammation*, can occur at sites of chronic osteomyelitis, cardiac myxomas, splenic cysts, and skin ulcers and near metallic prostheses.⁹²⁶

Extranodal NK/T-cell lymphoma—nasal type, previously referred to as midline granuloma, usually presents in the nose but can also involve the sinuses and palate. Other portions of the upper airway may be involved; much less commonly the gastrointestinal tract and skin are infected.^{672,673} Pathology shows invasion of blood vessels with necrosis. Most tumor cells are CD56+ and surface CD3– and express granzyme and perforin; however, in some cases cells are CD56–, CD3+. These tumors are more common in Southeast Asia and Central and South America, especially in men. The disease may be associated with HLH. The tumors are nearly always EBV positive, are clonal for EBV, and have type 2 EBV latency with variable expression of LMP1.^{224,414,1575} EBV LMP1 expression is associated with up-regulation of integrin α M, which may be important for angiogenesis of these tumors.⁹⁰⁷ Elevated levels of interferon-induced cytokines MIG and IP10 are present in areas of tissue necrosis.¹⁴⁴⁰ Tumor cells often show NF- κ B and Akt activation⁶²⁶ and express TNF- α with dysregulation of STATs and Rel A. Some patients have disease involving the peripheral blood, termed NK-cell leukemia, and the malignant cells are EBV positive. High levels of EBV DNA in the blood correlate with a poorer prognosis.^{620,1410} Treatment involves chemotherapy and radiation therapy; early-stage disease is usually curable, while disseminated disease has a poor prognosis.⁵⁴

Aggressive NK-cell leukemia/lymphoma presents with fever, night sweats, weight loss, pancytopenia, hepatosplenomegaly, and large granular lymphocytes in the blood and bone marrow. About 50% of cases are EBV positive and the disease is more common in Asians; some patients initially present with CAEBV. The level of EBV DNA in the plasma is elevated at onset of disease and parallels the course of the disease.⁵⁵

Inflammatory pseudotumor-like follicular dendritic cell sarcoma presents with fever and usually involves the spleen and liver.²¹⁸ The tumors contain clonal EBV DNA with a type 2 pattern of EBV latency.

Breast cancer has been associated with EBV based on earlier reports using PCR and antibodies to EBV proteins that detected EBV in a small fraction of the tumor cells; however, more recent studies using *in situ* hybridization and immunohistochemistry have generally not supported an association of EBV with the disease.^{301,1069}

EBV and HIV

Patients with late-stage HIV often have higher levels of EBV-specific antibodies and lower levels of virus-specific CTLs, shed higher levels of virus from the throat, and have 10-fold higher levels of EBV in the peripheral blood than healthy persons.¹¹¹ In contrast to transplant recipients, the level of EBV in the blood alone is not predictive of EBV-associated lymphoma and may not correlate with the CD4 count in patients with HIV.¹¹⁶⁹ The level of EBV DNA and the BZLF1-specific T-cell response

in the blood may rise after acute HIV infection and reach a new EBV DNA set point. EBV viral loads rise in HIV patients during the late stage of AIDS. The CD4 T-cell response to EBNA-1 and BZLF1 was lower in untreated patients with HIV than in healthy persons or in those on highly active antiretroviral therapy (HAART).¹¹⁷⁰ The EBV viral load of children with untreated HIV is often similar to that seen in healthy children with acute EBV infection.⁸⁹ EBV is predominantly in B cells, and EBV transcripts for LMP2, but not EBNA-1, LMP1, or lytic genes, are present in the cells.¹³⁹¹

In patients begun on HAART, the EBV DNA load did not change, and there was a decline in BZLF1-specific CD4 and CD8 T cells suggestive of less EBV reactivation. In contrast, there was an increase in EBNA-1-specific CD4 and CD8 T cells to levels similar to those seen in healthy persons.¹¹⁶⁵

A longitudinal study of EBV DNA loads and cellular immunity in HIV patients showed that patients who did not develop NHL had stable levels of EBV DNA and EBV-specific CTL precursors, while patients who developed NHL had increasing EBV loads and decreasing EBV-specific CTLs before the onset of lymphoma.⁷⁴⁹ In another study, HIV patients who developed NHL had increasing EBV DNA levels in the blood, and although they did not have a decline in the number of EBV-specific T cells, these cells lost their ability to produce IFN- γ in response to EBV peptides.¹⁴⁸⁶ These studies indicate that loss of immunity to EBV and rising viral loads correlate with development of lymphomas. Primary infection with EBV does not alter the HIV viral load or progression to AIDS.¹¹⁴⁵

The overall rate of EBV-positive lymphomas has declined with HAART. Lymphomas that occur early in the course of HIV infection—BL and HL—have not declined in incidence with HAART, while lymphomas that occur later when patients are very immunocompromised—immunoblastic and primary CNS lymphomas—have decreased in incidence.¹⁶⁷

Oral hairy leukoplakia is a nonmalignant disease that occurs in patients with late-stage AIDS and in some transplant recipients.^{488,1471} The disease presents with white corrugated “hairy” lesions on the lateral aspect of the tongue or occasionally on the palate or buccal mucosa and is due to lytic EBV replication in the outer layer of epithelial cells, but not the basal layers. Pathology shows hyperkeratosis of the squamous epithelium with acanthosis and intranuclear inclusions, but no inflammatory cells. Biopsies show linear (replicating) EBV DNA and herpesvirus particles on EM. EBV lytic antigens BZLF1, EA, and VCA, as well as EBNA-1, EBNA-2, and LMP1 are expressed in epithelial cells.^{1509,1536} Multiple EBV strains have been detected in single lesions with EBV variants due to recombination in and adjacent to the EBNA-2 gene between viruses.¹⁵⁰⁷ The disease responds to acyclovir, which inhibits EBV replication; however, relapses are common when acyclovir is stopped; HAART can resolve lesions.

Lymphoid interstitial pneumonitis is characterized by diffuse interstitial pulmonary infiltrates. The alveoli are infiltrated with EBV-positive B cells, immunoblasts, and plasma cells.³⁹³ The disease is more common in children with HIV, although it can occur in adults with autoimmune disease.

Burkitt lymphomas account for about 35% of cases of AIDS-associated lymphoma (Table 61.4). About 30% of BLs in HIV are EBV positive. The disease occurs in patients with HIV usually before they develop severe immunodeficiency. These

tumors usually have a type 1 EBV latency pattern, or less commonly a type 2 pattern, and have c-myc translocations.

Hodgkin lymphoma occurs early in the course of HIV, and like patients without HIV, EBV is more often present in tumors of the lymphocyte-depleted or mixed cellularity subtypes.

Non-Hodgkin lymphomas in patients with HIV are EBV positive in 50% of cases and are clonal for the viral genome.^{173,174,1332} EBV was detected more often in benign lymph nodes of HIV patients who subsequently or concurrently had NHL than in those without lymphoma.¹³³³ Patients with HIV progressing to NHL had loss of EBV-specific CD8 T and CD4 T cells, including EBNA-1-specific CD4 and CD8 T-cell responses.¹¹⁶⁷

Diffuse large B-cell lymphomas include centroblastic and immunoblastic lymphomas. Centroblastic lymphoma involves the lymph nodes and accounts for 25% to 30% of HIV lymphomas, and 30% of the tumors are EBV positive. Immunoblastic lymphomas account for 10% of HIV lymphomas, 90% are EBV positive, and the tumors are extranodal. Diffuse large B-cell lymphomas often have type 2 or type 3 EBV latency, although variable expression of latent EBV genes has been reported.^{521,522,1211}

CNS lymphomas in patients with AIDS are nearly always EBV positive, are immunoblastic lymphomas with type 3 EBV latency, and occur late in the course of AIDS when CD4 T-cell counts are low⁹⁵⁵ (Fig. 61.26). The cerebrospinal fluid is usually EBV positive. While studies before the era of HAART found that detection of EBV in the cerebrospinal fluid of patients with mass lesions was highly predictive of CNS lymphoma,²³⁷

more recent studies suggest that the positive predictive value may be 30% or less.^{262,661} Increased metabolic activity on a PET scan along with EBV DNA in the cerebrospinal fluid increases the likelihood of CNS lymphoma in these patients. HIV patients who subsequently developed CNS lymphomas lacked EBV-specific CD4 T cells regardless of their T-cell counts and whether they had undergone immune reconstitution.⁴⁴⁸ Other immunoblastic lymphomas in patients with AIDS occur in the late stages of the disease and are usually EBV positive.

Plasmablastic lymphomas are usually EBV positive and occur in the mouth or jaw of patients with HIV; less often they present in the sinus, gastrointestinal tract, or soft tissues.^{324,1224} These tumors are EBER positive, have a type 1 latency pattern, and do not express CD20. They generally occur late in the course of HIV and have a poor prognosis.

Primary effusion lymphomas are located in the pleural, pericardial, or peritoneal cavity. The cells are positive for HHV-8 DNA and 90% or more of the tumors contain EBV DNA. When positive for EBV, the EBV genome is required for cell proliferation.⁹⁵² EBV inhibits HHV-8 lytic replication in primary effusion lymphoma cells.¹⁵⁷⁴ The tumor cells express EBNA-1 and may express LMP1 and LMP2.^{157,607}

EBV-positive smooth muscle tumors, leiomyosarcomas, and leiomyomas occur in patients with AIDS,^{999,1192} in transplant recipients,^{845,1385} and in patients with congenital immunodeficiencies. These tumors usually present in the lungs or gastrointestinal tract but also can involve the liver, kidney, lymph nodes, central nervous system, and adrenal glands.⁴⁴³ The smooth muscle cells contain clonal or oligoclonal EBV DNA. Multiple tumors in the same patient may be from distinct EBV clones, indicating that they can arise independently.³⁰⁸ The disease usually occurs in the late stage of AIDS or at a mean of 3 years after organ transplant. Tumors can be either donor or recipient in origin in transplant patients. EBV gene expression varies; some tumors show type 3 EBV latency, while others express EBNA-2 but not LMP1. In contrast, leiomyomas and leiomyosarcomas from immunocompetent persons do not contain EBV DNA.

Model for EBV Oncogenesis

While a large number of malignancies are associated with EBV and new associations continue to be made, certain criteria have proved important for linking EBV to tumors. First, EBV should be in virtually every tumor cell. Second, the viral DNA should be clonal (or oligoclonal), indicating that the malignancy arose from an EBV-infected cell. Third, in the case of epithelial cell malignancies, viral DNA should be in dysplastic lesions, indicating that EBV infection occurred during oncogenesis. Fourth, at least one EBV-associated latency gene should be expressed, indicating that the virus has an active role in maintaining the tumor.

Some EBV-associated malignancies are strongly linked with the virus, which clearly is required for development of the tumor (Fig. 61.27). These malignancies have a short latency period between EBV infection or virus reactivation and development of malignancy, and occur in highly immunosuppressed persons with little or no EBV-specific T-cell immunity. The tumor cells express most or all of the EBV-associated latency proteins and have few if any host gene mutations. Examples include EBV lymphoproliferative disease occurring early after transplantation or in patients with congenital immunodeficiencies. The low level of cellular immunity to EBV allows

FIGURE 61.26. Biopsy from a patient with immunoblastic lymphoma of the central nervous system. (Courtesy of Dr. Elaine Jaffe.)

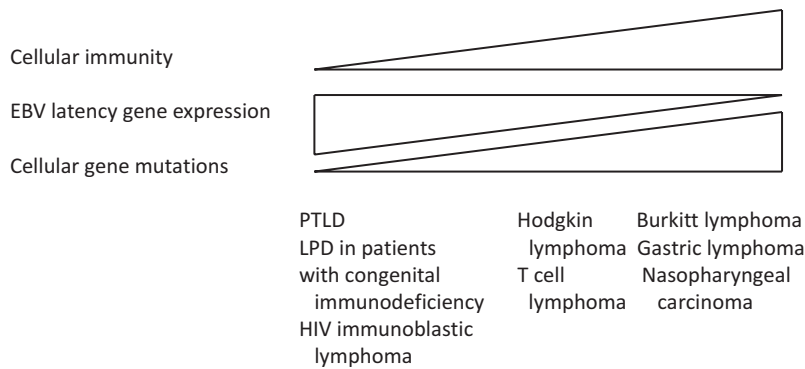

FIGURE 61.27. Model of Epstein-Barr virus (EBV) oncogenesis. EBV-associated malignancies in immunocompromised patients show full expression of EBV latency genes and few or no mutations or changes in cellular gene expression (**left**), while EBV-associated malignancies in persons with otherwise normal immunity have limited expression of EBV latency genes and more mutations or changes in cellular gene expression (**right**).

expression of the EBV-transforming proteins, which rapidly results in transformation without the need for secondary cellular genetic changes.

In contrast, other malignancies (e.g., HL) occur in otherwise healthy persons, have longer latency periods, and express an intermediate number of EBV latency genes. These patients have impaired T-cell immunity,³⁹⁴ but to a much lesser extent than those with EBV PTLD. Viral gene products can substitute for mutations in host cell genes that occur in the analogous EBV-negative tumors (e.g., crippled germinal center cells in HL).

A third class of EBV-associated malignancies (e.g., BL, NPC, gastric carcinoma) has mutations in cellular genes and more limited EBV latent gene expression. In EBV-associated epithelial cell malignancies (NPC, gastric carcinoma), genetic mutations are associated with inactivation of tumor suppressor genes and hyperplastic changes occur before EBV infection of the cells. In BL, EBV may initially drive proliferation of B cells, resulting in chromosomal translocation and oncogene activation (*c-myc* in BL). In these diseases, EBV is clearly a cofactor and virus infection is one of several steps in development of the fully malignant phenotype. However, the presence of clonal EBV in every tumor cell, without loss of viral DNA after tumors are established, indicates that the fully malignant phenotype is dependent on EBV.

Other Diseases Associated With EBV

Chronic lymphocytic leukemia may have a subpopulation of cells infected with EBV, and these cells express LMP1 and EBERs. EBV has been associated with transformation of chronic lymphocytic leukemia to diffuse large B-cell lymphoma.³¹⁹ EBV has also been detected in T-cell prolymphocytic leukemia cells.⁸³⁰

Rheumatoid arthritis patients often have elevated EBV DNA loads in the blood.¹⁵⁸ These patients have an increased risk of lymphomas (HL and diffuse large B-cell lymphoma), even in the absence of immunosuppressive therapy, and 24% of the lymphomas are EBV positive.

Multiple sclerosis (MS) has been associated with EBV in several studies. Primary infection with EBV is associated with an increased risk of MS⁸⁶²; in contrast, persons who are EBV seronegative have a very low risk of MS. A meta-analysis showed a 2.2-fold increased risk of MS after IM.⁵³⁰ A case-control study showed that 83% of children with MS had evidence of EBV infection, compared with 43% of controls.²² A study of the prevalence of EBV-specific antibodies prior to the onset of MS found that serum antibodies to the EBNA complex in persons 25 years old or older were two- to threefold higher in those who

subsequently developed MS compared to those who did not.⁸⁶³

The risk of MS was 36-fold higher in persons with high titers of anti-EBNA complex IgG antibodies and 8-fold higher in those with high EBNA-1 titers than those with low titers.¹⁰⁶⁶ A meta-analysis of several studies found an association between MS and anti-EBV VCA IgG, anti-EBNA IgG, and anti-EBNA-1 antibody, but not anti-EBV EA IgG, viral DNA in the serum, or DNA in cerebrospinal fluid or brain.¹²⁸¹ Patients with MS have increased numbers and broadened specificity of CD4 T cells to EBNA-1.⁹⁴³ Elevated levels of both antibodies and T cells to EBNA-1 were associated with development of MS.⁹⁴⁵ EBNA-1-specific T cells cross-reacted with myelin more frequently than autoantigens not associated with MS, and the myelin cross-reactive T cells produced IFN- γ and IL-2.⁹⁴⁴

While most studies have not found EBV DNA or RNA in the brain, one study reported that nearly all postmortem brains from patients with MS showed EBV RNA (EBER) and BFRF1 protein in B-cell follicles, and LMP1 and EBNA-2 in perivascular areas in white matter lesions; EBV gene expression was not detected in brains from persons without MS.¹³¹⁸ CD8 T cells were present at the site of EBV-infected B cells in the brain. In contrast, EBV RNA was generally not detected in active plaques or in B cells in the cerebrospinal fluid in another study of patients with MS.¹²⁸² One study reported higher levels of antibodies to peptide sequences from EBV BRRF2 and EBNA-1 in the serum and cerebrospinal fluid from patients with MS compared with controls; antibodies to the viral proteins were present in oligoclonal cerebrospinal fluid IgG.¹⁸⁵ Increased levels of EBV antibody were detected in the serum and cerebrospinal fluid of patients with MS¹¹⁰⁰; however, intrathecal synthesis of EBV antibody was uncommon, absent, or nonspecific in other studies.^{180,1122,1282} Further studies will be needed to confirm many of these findings, and the role EBV in the pathogenesis of MS is still unclear.

Systemic lupus erythematosus (SLE) is associated with elevated antibody titers to EBV; however, a prior history of IM was not associated with increased risk of SLE.¹⁴⁸³ In one study, 99% of children with SLE had evidence of prior infection with EBV compared with 70% of age-matched controls.⁶⁷⁶ EBV DNA was detected in the blood of 100% of patients with SLE, compared with 72% of controls. Patients with SLE often have higher EBV loads, increased numbers of latently infected B cells, and certain EBV-specific antibodies that cross-react with SLE autoantigens.⁶⁷⁵ Patients with SLE more often have antibody to EBNA-1 and produce antibody to more regions of EBNA-1 than healthy persons.¹⁰⁰¹ Antibody to 60-kD Ro,

which cross-reacts with EBNA-1, was detected in some patients with SLE prior to the onset of disease; rabbits immunized with either a 60-kD Ro or a cross-reacting EBNA-1 peptide developed autoantibodies and SLE-like autoimmune disease.¹⁰⁰⁰ Immunization of rabbits and mice with an EBNA-1 peptide homologous to part of the Sm antigen resulted in autoantibodies and SLE-like autoimmune disease.¹¹⁷⁵ While there is vigorous B-cell activation in SLE and impaired control of EBV, EBV-associated malignancies are not increased in these patients. At present, there is not a strong causal relationship between EBV and SLE.

DIAGNOSIS

The diagnosis of IM in patients with typical symptoms is made by a positive heterophile antibody. In patients with atypical symptoms, or in those with typical symptoms and a negative

heterophile test, titers of EBV-specific antibodies are measured. Antibody to EBV VCA IgM antibody is the most useful test because the antibody is present only during the first 2 to 3 months of the illness (see Fig. 61.15). EBV VCA IgG antibody is often elevated at the time of diagnosis, but because it persists for life, it is not useful for diagnosis of acute infection. Seroconversion to EBV EBNA positivity can be useful because antibodies take 3 to 6 weeks after the onset of illness to become positive and they persist for life. Antibody to EBNA-2 is present early in IM, while antibody to EBNA-1 is present later during convalescence.

Detection of EBV DNA in the blood can be useful for diagnosis of IM if serologic results are equivocal. Measurement of EBV DNA in the blood is also used to follow patients after transplant to predict the development of EBV PTLD or to follow patients after therapy.^{505,769} Detection of EBV DNA in the cerebrospinal fluid of AIDS patients with lesions in the brain is useful for prediction of lymphoma. Culture of throat

FIGURE 61.28. Identification of replicating, latent clonal, or latent oligoclonal Epstein-Barr virus (EBV) in biopsies. Linear (upper left) and circular (upper right) EBV genomes have differing numbers of terminal repeats (gray bars) bounded by restriction endonuclease sites (RE). Southern blotting with a probe to the terminal repeats shows different patterns in cells with replicating (linear EBV) or latently infected clonal (single form of terminal repeats) or oligoclonal (different forms of terminal repeats) EBV DNA (bottom). (Adapted from Katz B, Raab-Traub N, Miller G. Latent and replicating forms of Epstein-Barr virus DNA in lymphomas and lymphoproliferative diseases. *J Infect Dis* 1989;160:589–598, by permission of the Infectious Diseases Society of America.)

washings for EBV is not useful for diagnosis of IM because the virus persists for life in the throat of infected persons. PCR for the terminal repeats is used to determine if EBV is clonal in tissues, because individual clones have a fixed number of terminal repeats (Fig. 61.28).

EBV is usually detected in tissue by *in situ* hybridization using a probe for EBER (Fig. 61.29) because this RNA is present at thousands of copies per cell. EBV latency proteins, including EBNA-1, EBNA-2, or LMP1, can also be detected in tissues.

INHIBITORS OF REPLICATION

Acyclovir and ganciclovir inhibit the viral DNA polymerase²⁸⁵ but do not inhibit latent infection. Phosphorylation of acyclovir and ganciclovir is mediated by the EBV BGLF4 protein kinase, not the viral thymidine kinase (encoded by BXLFI).¹⁰¹⁰ While treatment of chronic EBV carriers with acyclovir stops EBV shedding from the oropharynx, 1 month of therapy has no effect on the EBV viral load in the blood.¹⁵⁸¹ However, 1 year of antiviral therapy resulted in a modest reduction in the EBV viral load in the blood but did not affect the EBV DNA

copy number per B cell.⁶¹¹ CMX-001, a hexadecyloxypropyl ester of cidofovir, is greater than 100 times more potent as an inhibitor of EBV replication than acyclovir.¹⁵⁴² Maribavir, an l-ribofuranoside benzimidazole, blocks phosphorylation of viral proteins by the EBV protein kinase and inhibits viral transcription, which results in reduced EBV replication.¹⁵²⁵

TREATMENT

Infectious Mononucleosis

Treatment of IM is supportive. Contact sports should be avoided during the acute phase of the disease due to the risk of splenic rupture. While antiviral therapy reduces or eliminates virus replication and shedding from the oropharynx, it has no effect on symptoms.^{1468,1488} Corticosteroids reduce the duration of fever and sore throat; however, they may inhibit the development of cellular immunity to the virus and are not recommended for most cases of IM. The combination of corticosteroids and antiviral therapy did not reduce time off from work or school or the duration of the disease.¹⁴⁸⁰ Corticosteroids are used for life-threatening complications such as upper airway obstruction due to tonsil enlargement, severe hemolytic anemia, and some cases of cardiac or central nervous system EBV disease.

EBV Posttransplant Lymphoproliferative Disease

Reduction in immunosuppression can allow an increase in EBV-specific T-cell activity⁵⁰⁶ against virus-infected B cells and in some cases, especially disease that occurs early after organ transplant, can cause tumor regression.^{480,573} Rituximab, which depletes CD20-positive B cells, can be effective,²³¹ especially in combination with chemotherapy. Recent studies show that rituximab and reduced-dose chemotherapy have been successful in children.⁵⁰⁷ Surgery can be effective when PTLD lesions are confined to a single site. Cytotoxic chemotherapy (e.g., CHOP) is often effective early after transplant²³² or in cases of rituximab failure.¹⁴⁷⁰ Radiation as well as high-dose methotrexate is often used for disease involving the central nervous system.¹⁴²⁰ Antiviral therapy has no effect once PTLD is established, because the EBV genome replicates in latently infected cells using the host, not viral, DNA polymerase.

Most tumors are of donor origin in hematopoietic stem transplant (HSCT) recipients. Thus, in these patients infusion of donor lymphocytes has been successful, although graft-versus-host disease can occur.^{481,1120,1132} (Table 61.6). Repeated infusions of cells may be required, and graft-versus-host disease may occur when large numbers of cells are infused. Treatment of EBV PTLD with EBV-specific CTLs after HSCT resulted in complete remissions in 11 of 13 patients.⁵⁷⁵ Partially HLA-matched EBV-specific CTLs from third parties have been successful for treatment of PTLD in HSCT recipients.^{75,1009} Functional gene-marked CTLs persisted for up to 9 years. Immune escape from EBV-specific CTLs was reported in one bone marrow transplant recipient whose tumor cells mutated, deleting two EBNA-3B epitopes, which resulted in a fatal outcome.⁴⁷⁹

Most EBV PTLD in organ transplant patients is recipient in origin. In these patients reduction of immunosuppressive therapy can increase the level of EBV-specific T cells and may cure the disease. In some cases EBV-specific CTLs have been expanded from organ transplant recipients and successfully

FIGURE 61.29. Epstein-Barr virus–encoded RNA (EBER) staining from a biopsy showing Epstein-Barr virus (EBV) lymphoma. Arrows show cells that hybridize with the EBER probe. (Adapted from Cohen JI. Epstein-Barr virus infection. *N Engl J Med* 2000;343[7]:481–492.)

TABLE 61.6 EBV-Specific Approaches to Treatment of EBV Malignancies

Approach	Method	Results	References
Infusion of EBV-specific CTLs	CTLs directed against EBV latent proteins (LCLs)	Effective in PTLD	118,256,533,1120,
	CTLs directed against LMP2	Some responses in HL, NPC	1237,1394
Therapeutic vaccination	DC with LMP2 peptides	CR for HL and NHL	119
Induction of EBV replication	Arginine butyrate and ganciclovir	Tumor regression in NPC	891
	HDAC inhibitor and cytotoxic chemotherapy	Tumor responses in PTLD and NHL	1156
	Azacytidine	Tumor responses in mice	386
	Gemcitabine or doxorubicin and ganciclovir	Demethylation of EBV promoter, activation of BZLF1	191
	Adenovirus expressing BZLF1 or BRLF1	Tumor response in mice	385
Reduction of EBV episome copy number	Low-dose hydroxyurea	Tumor response in mice	387
Cell cycle arrest of EBV-transformed B cells	Rapamycin	Responses in EBV CNS lymphoma	1362
Inhibition of NF- κ B	Ritonavir, BAY 11-7082, bortezomib	Tumor responses in mice	1492
Reduction of EBNA-1 expression	Hsp90 inhibitor	Tumor responses in mice	307, 736,720,1639
	miR-155 inhibitor	Tumor responses in mice	1408
	siRNA	Reduced EBV copy number <i>in vitro</i>	931
Reduction of LMP1 expression	Antisense RNA	Inhibited growth of NPC cell line <i>in vitro</i>	1593
		Induced apoptosis of EBV-transformed B cells	744

EBV, Epstein-Barr virus; CTL, cytotoxic T lymphocytes; LCL, lymphoblastoid cell line; PTLD, posttransplant lymphoproliferative disease; NPC, nasopharyngeal carcinoma; LMP, latent membrane protein; CR, complete remission; HL, Hodgkin lymphoma; NHL, non-Hodgkin lymphoma; DC, dendritic cell; HDAC, histone deacetylase; NF, nuclear factor; miR, microRNA; siRNA, small interfering RNA.

treated the disease.^{757,1290} In 2 organ transplant recipients with active PTLD and in 10 at risk for the disease who received autologous EBV-specific CTLs, one patient with active disease had a complete response and one had a partial response, while none of the patients at risk developed PTLD.¹²⁹⁰ Partially HLA-matched allogeneic T cells from a donor bank that covered 95% of common HLA haplotypes resulted in a complete remission in 42% of patients with PTLD (most of whom had undergone organ transplant) who had progressive disease despite conventional therapy⁵³³; 86% of these patients in complete remission at 6 months were still in remission at 4 to 9 years.⁵³² Better responses were observed in recipients who received higher numbers of CD4 T cells.

EBV-specific T cells have also been derived from the blood of EBV-seronegative persons.^{1176,1289} CTLs that recognize adenovirus, CMV, and EBV have been developed by transducing EBV lymphoblastoid cell lines with a vector expressing adenovirus and CMV genes; infusions of the CTLs into transplant recipients and their subsequent expansion in the blood were associated with lower levels of EBV DNA in the blood and resolution of EBV PTLD in one recipient.⁸⁵⁷ A rapid method of producing EBV-specific T cells involves stimulation of donor cells with EBV-specific peptides and antibody-mediated capture of cells expressing surface IFN- γ ; this technique allowed isolation of EBV-specific T cells from donor blood in 36 hours and resulted in remissions in patients with early-stage PTLD.¹⁰⁵²

While most EBV-specific T-cell therapies have focused on CD8 T cells that recognize EBV antigens, some CD4 T cells recognize EBV-transformed B cells not through viral antigen, but likely by cellular antigens that are induced by the virus.⁹¹⁸ The latter may provide additional targets for T-cell therapy. Lymphokine-activated autologous killer cells have been effective in small numbers of organ transplant recipients with disease.¹⁰⁷⁵

Hodgkin Lymphoma

HL cell lines can process and present EBV proteins to HLA class I–restricted EBV-specific CTL clones; thus, they should be amenable to CTL therapies.⁸⁵² Adenovirus expressing a portion of EBNA-1 linked with epitopes from LMP1 and LMP2 was used to stimulate CD8 T cells from patients with HL; this reversed the functional impairment of the T cells and the cells responded to tumor cells expressing EBNA-1 and LMP1 and LMP2 *in vitro*.¹³⁶⁵ Infusion of allogeneic EBV-specific CTLs into patients with refractory HL resulted in reduction in disease in some patients; however, the donor cells could not be detected in the recipients.⁹³⁷

CTLs were made to EBV-transformed B cells and infused into patients with EBV-positive HL; of 11 patients with measurable tumors, 2 had a complete response, 5 had stable disease, 1 had a partial response, and 3 had no response.^{118,1241} However, CTLs produced using dendritic cells transduced with LMP2 resulted in a higher frequency of LMP2-specific CTLs

and induced a complete response in 4 of 6 patients with HL or NHL and relapsed disease and maintained remissions in 9 of 10 patients.¹¹⁹

Nasopharyngeal Carcinoma

A poxvirus (MVA) vector expressing the carboxyl terminus of EBNA-1 fused to LMP2 reactivated LMP2-specific CD8 T-cell responses from EBV-infected persons *in vitro*.¹⁴³⁰ A phase I trial showed that CD4 and CD8 T-cell responses were induced *in vivo*.⁹¹⁷ Dendritic cells from patients with NPC were pulsed with LMP2 peptides *in vitro* and when injected into patients they resulted in epitope-specific T-cell responses in the blood coincident with tumor regression in some patients.⁸⁹¹ Dendritic cells infected with adenovirus expressing LMP2 and a portion of LMP1 did not increase the frequency of LMP1/LMP2-specific T cells in the blood and had limited efficacy.²²³ Poxvirus³³⁵ and adenovirus³³³ vectors expressing multiple HLA-A2–restricted LMP1 and/or LMP2 epitopes induced LMP-specific CTL responses in mice expressing HLA-A2 and inhibited growth of tumor cells expressing LMP1.

Infusion of autologous EBV-specific T cells in patients with late-stage NPC resulted in control of disease in 6 of 10 patients; 3 of 4 patients with LMP2-specific immune responses after infusion had a clinical benefit.²⁵⁶ A second study by the same authors used higher doses of EBV-specific T cells after lymphodepletion by chemotherapy and showed control of disease in 6 of 11 patients.¹³¹⁴ In another trial, 10 patients with advanced NPC were treated with autologous EBV-specific CTLs; 4 patients who had been in remission remained disease free, and of 6 with refractory disease before treatment, 2 had complete responses, 1 had a partial remission, 1 had stable disease, and 2 had no response.¹³⁹⁴ A phase I/II study of 23 patients (including 10 patients reported previously¹³⁹⁴ with recurrent or refractory NPC) showed that infusion of autologous EBV-specific T cells resulted in disease-free outcomes in 62% of patients who had been in remission at the time of infusions, while 49% who had active disease at the time of the infusions had a complete or partial response.⁹²⁷ Patients with metastatic disease had a worse outcome than those with locoregional disease. Infusions of anti-CD45 monoclonal antibodies to deplete lymphocytes prior to EBV-specific CTLs for NPC enhanced the expansion of the cells *in vivo*.⁹²⁸

Other Therapies

Other therapies to treat EBV diseases include the use of combined cytotoxic chemotherapeutic agents and ganciclovir to induce virus replication, express the viral protein kinase to phosphorylate ganciclovir (which is toxic to cells), and kill EBV-infected cells.³⁸⁵ Combined administration of ganciclovir and arginine butyrate (a histone deacetylase inhibitor) resulted in EBV-positive tumor responses in 10 of 15 patients.¹¹⁵⁶ Histone deacetylase inhibitors also increase the effectiveness of chemotherapeutic agents by inducing lytic replication in animal models of EBV lymphoma.³⁸⁶ Adenovirus-expressing EBV IE genes reduced EBV tumor growth in mice.³⁸⁷ Demethylating agents such as 5-azacytidine also activate viral gene expression.¹⁹¹ Other approaches include low-dose hydroxyurea to reduce EBV episome copy number,¹³⁶² and rapamycin, which induces cell cycle arrest at the G1 phase in EBV-transformed B cells and inhibits growth of EBV lymphomas in SCID mice.^{1084,1492} Ritonavir, an HIV protease inhibitor, down-regulates survivin

and cyclin D2, inhibits activation of NF- κ B, induces apoptosis in EBV-transformed B cells, and inhibits growth of lymphoma cells in immunocompromised mice.³⁰⁷ Hsp90 inhibitors reduce EBNA-1 expression and inhibit the growth EBV-transformed B cells in SCID mice.¹⁴⁰⁸ Inhibition of cellular microRNAs might also inhibit EBV disease. An miR-155 inhibitor reduced EBNA-1 mRNA and EBV copy number in latently infected cells.⁹³¹

A variety of compounds that block the activity of EBNA-1 or LMP1, including antisense molecules to LMP1,⁷⁴⁴ small interfering RNA (siRNA) to EBNA-1,¹⁵⁹³ and intracellular¹¹⁶⁴ and extracellular antibody to LMP1,²⁹⁷ are active *in vitro* but have not been used in clinical studies. Bortezomib, a proteasome inhibitor, and Bay 11-7082 block NF- κ B, induce apoptosis of EBV-transformed B cells, and enhance survival of mice injected with the cells.^{736,1639}

PREVENTION AND VACCINES

Preemptive therapy for EBV lymphoproliferative disease has included antiviral therapy with acyclovir or ganciclovir. Results have been mixed, with more recent studies reporting a reduction in disease^{438,1002} and other studies⁴⁸⁶ showing no effect. Depletion of B cells from bone marrow used for transplantation reduces the risk of EBV PTLT, presumably due to removal of virus-infected cells.⁵¹⁹ A single dose of rituximab (anti-CD20 antibody) given to allogeneic HSCT patients at high risk for EBV PTLT with rising viral loads reduced the rate of disease from 49% based on a historical cohort to 18% in the treated group and prevented death at 6 months.¹⁴⁸⁹ A second study showed similar results.¹⁵⁵⁵ However, relapses due to CD20-negative EBV-infected B cells have occurred that require other therapy.²⁵⁴ An alternative approach is to monitor patients with rising viral loads and to give rituximab or EBV-specific CTLs only when systemic symptoms develop.¹⁵⁰³ Infusion of EBV-specific T cells (directed against EBV latency-associated proteins) has been effective in reducing EBV load in the blood and preventing EBV-associated PTLT in HSCT recipients.^{480,574,1238} A study of EBV-specific CTLs for prevention of EBV PTLT found that none of 101 patients who received CTLs developed the disease.⁵⁷⁵ Donor-derived EBV-specific CTLs have prevented disease in matched unrelated and haploidentical stem cell transplants.⁸⁵⁶ Intravenous immunoglobulin did not provide any additional effect when added to antiviral therapy.⁶³⁶

Reduction of immunosuppression is often effective early after transplantation when viral loads increase.¹⁸⁷ In a study of 73 liver transplant recipients in which immunosuppression was tapered when EBV viral loads were elevated, one patient developed allograft rejection, but the incidence of PTLT declined from 16% to 2%.⁸⁵⁴ EBV-specific T cells prevented development of EBV-positive lymphomas when they were given as prophylaxis to T-cell-depleted bone marrow transplant recipients with high EBV loads after transplant and at high risk of the disease¹²³⁷; the cells can persist for at least 18 months.⁵⁷⁴ Autologous EBV-specific T cells have also been used to prevent EBV lymphomas in solid organ transplants with high viral loads.²⁵⁵

Vaccination to prevent EBV infection or disease will be important in certain high-risk groups including transplant recipients, boys with mutations in SAP or XIAP, and areas

where the frequency of NPC and BL are high.²⁴⁸ Vaccination that reduces the rate of IM might reduce the frequency of HL, which is increased during the first 5 years after IM.

gp350 has been the major immunogen in vaccine studies; it is the major target for neutralizing antibody¹⁴⁶ and it is a target of CTLs.⁷⁵⁷ Infusion of immunodeficient mice, reconstituted with PBMCs from EBV-negative persons, with monoclonal antibody to gp350 prevents development of EBV lymphomas after challenge with virus.⁵³¹ Soluble gp350 protected cotton-top tamarins that had been challenged intravenously with high doses of EBV from lymphoma.³⁶⁴ After immunization of cotton-top tamarins or common marmosets with gp350, protection from lymphoma¹²⁰³ or infection,³⁵⁸ respectively, did not always correlate with development of neutralizing antibody. Rhesus lymphocryptovirus is the homolog of EBV in rhesus macaques and contains an ortholog of each EBV gene. Immunization of rhesus macaques with soluble rhesus lymphocryptovirus gp350 resulted in better protection from infection and reduced viral loads 2 years after infection in animals that became infected after challenge when compared with virus-like replicon particles expressing rhesus lymphocryptovirus gp350, EBNA-3A, and EBNA-3B.¹²⁸⁵

A study of 19 seronegative children (1 to 3 years old) in China randomized to vaccination with vaccinia virus expressing gp350 or control showed that the vaccine induced neutralizing antibody to EBV; at 16 months all 10 unvaccinated children were infected with EBV, while only 3 of 9 vaccinated children were infected.⁵⁰³ Soluble gp350 vaccine induced neutralizing antibody in volunteers.¹⁰⁶² A study of 181 EBV-seronegative adults randomized to receive three doses of soluble gp350 in monophosphoryl lipid A/alum adjuvant or placebo showed that the vaccine reduced the rate of EBV IM by 78% but did not affect the rate of virus infection.¹³⁶⁹ A phase I trial of children with chronic kidney disease using three injections of a lower dose of gp350 in alum showed that the vaccine induced neutralizing antibody in 33% of subjects receiving the highest dose of gp350 and immune responses declined rapidly; the authors concluded that a more prolonged vaccine schedule or an improved adjuvant was needed for these patients.¹²¹⁴

An alternative or complementary strategy is to induce potent T-cell responses to control primary infection so as to reduce the viral load after infection and potentially reduce the risk of EBV-associated malignancy. A study of 14 HLA B*0801 EBV-seronegative adults randomized to receive an HLA B*0801 EBV EBNA-3A peptide (FLRGRAYGL) and tetanus toxoid in a water-in-oil adjuvant showed that 8 of the 9 volunteers developed epitope-specific T-cell responses.³⁵⁵ At 2 to 12 years after follow-up, one of two placebo recipients developed IM, while four of four vaccinees that became infected with EBV did not develop IM. Virus-like particles expressing nearly all the EBV genes except for BZLF1, EBNA-2, EBNA-3A, EBNA-3B, EBNA-3C, and LMP1 and the terminal repeats induced neutralizing antibody and T-cell responses in mice.¹²⁵⁵

PERSPECTIVE

The true importance of the innate immune response, NK cells, and CD4 cells in controlling EBV is unclear. It is not apparent why EBV IM is primarily a disease of adolescents and young adults. Treatment of prolonged fatigue that occurs sometimes

after IM is unsatisfactory. The role of EBV in multiple sclerosis and SLE is still unclear.

While small-scale trials have shown that a vaccine can reduce the incidence of IM, a larger trial is needed to confirm these findings. Similarly, it is unknown if such a vaccine would reduce the rate of PTLD in seronegative transplant recipients or prevent or reduce the rates of EBV-associated malignancies, including HL, BL, NPC, and gastric carcinoma. The immune correlates of protein against EBV infection, IM, and EBV-associated malignancies are not well understood.

EBV continues to be associated with additional malignancies, and the mechanisms involved in viral oncogenesis continue to be unraveled. Treatment of EBV-associated malignancies is usually not directed against viral proteins. Additional drugs that can target viral or cellular proteins involved in oncogenesis are needed. While preliminary studies suggest that EBV-specific CTLs might be used to control NPC and HL, more effective therapies are needed. Additional therapies to induce EBV replication and kill virus-infected cells, infusions of EBV-specific CTLs followed by vaccination to boost CTL numbers, and treatments that block EBV immune evasion mechanisms might be useful for treating EBV-associated malignancies.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the assistance of their colleagues, and we thank Alan Rickinson, Martin Rowe, and Paul Murray for reviewing portions of this chapter. J. I. C. is supported by the Intramural Research Program of NIAID. R. L. is the Dan and Bertha Spear Research Professor and is supported by grants from the NCI, NIAID, NEI, and AHA. EK is supported by the Harriet Ryan Albee Chair and grants from the NCI. We apologize to those investigators whose contributions were not included in this chapter due to space limitations.

INTRODUCTION

Human cytomegalovirus (HCMV) is a ubiquitous virus infection with worldwide distribution. The virus is the most significant infectious cause of congenital disease, an important opportunist in the immunocompromised host and an occasional cause of febrile illness as well as infectious mononucleosis in the general population. HCMV infects an overwhelming majority of the population, spreading efficiently throughout life and all over the world through direct contact with bodily secretions. Like other human herpesviruses, HCMV is never completely cleared and remains latent for the life of the host. Persistently and sporadically shed virus is an important recurrent source of virus for transmission. Susceptibility to HCMV disease is associated with a compromised immune system, particularly related to defects in cell-mediated CD4 and CD8 T-cell function. During pregnancy, intrauterine transmission to the fetus results in sensorineural damage. In immunocompromised

individuals (following solid organ transplantation and hematopoietic cell allografting, immunosuppressive therapies, and genetic or acquired immunodeficiency), this virus remains clinically important despite available antiviral therapies aimed at reducing the overall disease burden. More effective and safe, orally bioavailable antiviral drugs are needed.

Transplacental transmission during pregnancy, rare with other human herpesviruses, underscores the medical importance of HCMV as well as the motivation for universal vaccination.⁴⁸¹ Virus transmits during primary maternal infection (in HCMV-seronegative women) in a pattern reminiscent of rubella; however, HCMV causes recurrent maternal infection (in HCMV-seropositive women) following either reinfection with additional viral strain or reemergence of persistent/latent infection. It is now recognized that this virus is transmitted in at least 1% of pregnancies worldwide regardless of population serostatus. Sensorineural damage (hearing loss, eye sight compromise, and learning disabilities) impacts roughly 12% to 25% of infected newborns,¹⁶² with half developing disease over the first few years of life. A small proportion of congenital infections cause severe systemic, life-threatening cytomegalic inclusion disease (CID). Overall awareness of disease risk is poor, both in the general population and among physicians, possibly owing to the limited options that are available to treat congenital HCMV disease. Because person-to-person transmission depends on direct contact with infected bodily secretions, viral shedding patterns in urine, saliva, breast milk, and genital secretions mediate exposure. Good hygiene practices (e.g., handwashing) can reduce rates, although widespread shedding and transmission results in universal transmission in populations worldwide. Transmission is most frequent in childhood and is mostly asymptomatic. A varying proportion of the population, ranging as high as 50% to 60% in areas of North America and Europe, escapes infection early in life and remains susceptible as adults. Primary infection during pregnancy in HCMV-naïve women is associated with an average 33% risk of transplacental transmission,²⁸⁹ whereas roughly 1% of recurrent infections result in transmission.⁹⁵ Therefore, HCMV universal vaccination is highly desirable²⁹ and includes the challenge of preventing primary as well as recurrent intrauterine maternal transmission.⁵⁶²

Space limitations dictate emphasis on HCMV, with some reference to key observations in animal models, in this chapter. A growing number of publications and reviews are available. The reader is strongly advised to consult earlier reviews and chapters focusing on cytomegaloviruses to obtain a more complete understanding of this field. In particular, *Cytomegalovirus: Biology and Infection*,²⁴⁷ the last version of this chapter⁴⁰⁴ as well as earlier versions^{18,397,402,404,446,627} and the reference book, *Human Herpesviruses: Biology, Therapy and Immunopathology*,²⁸ provide more extensive information. Given the limited number of references that can be included in the print version of this chapter, we generally reference a key recent report or review, expecting that this will lead the reader to relevant earlier work. The online materials provide more extensive references.

History

HCMV has been recognized as an opportunistic pathogen in immunocompromised hosts as well as an important infectious cause of birth defects for half a century.^{704,705} Observations of cytopathology associated with HCMV disease in the immunocompromised host and newborns extends back nearly 100 years

before cell culture or virus isolation methods were available. Severe HCMV-associated CID was first recognized by its association with “owl’s eye” cytopathology in autopsy specimens prior to any knowledge of viral etiology. Surrogate animal models employing natural cytomegaloviruses of mice, rats, and guinea pigs played important roles in early appreciation of pathogenesis.²⁴⁷ More recent studies using rhesus macaque cytomegalovirus (rhCMV) have been possible due to isolation of specific pathogen-free monkeys.^{41,490} By the early 1950s, diagnosis of HCMV disease was facilitated by the identification of inclusion-bearing cells in urine along with the demonstration of virus-like particles by low-resolution electron microscopy (EM). One investigator in particular, Margaret Smith, pursued studies on salivary gland virus of mice, which today is called murine CMV (MCMV), for at least two decades before the mid-1950s, when human salivary gland virus was isolated from urine of congenitally damaged newborns by her, at Washington University, as well as by Thomas Weller at Harvard and Wallace Rowe at National Institutes of Health (NIH). MCMV and HCMV replicated and produced a similar cytopathology, but only on fibroblasts from the homologous species. Species-specificity is now recognized as a key characteristic of all cytomegaloviruses. In the period from 1956 through 1970, the viral etiology of HCMV disease in newborns and immunocompromised transplant recipients was elucidated.^{704,705} Biologically similar viruses associated with a characteristic tissue and cell type distribution were isolated from many mammals. By the early 1970s, diagnosis of HCMV by virus isolation was established as a gold standard. By the turn of the 21st century, quantitative polymerase chain reaction (PCR) detection of viral DNA in blood and secretions became the standard for diagnosis of infection.¹⁶⁴

As the health economic and societal consequences of HCMV damage, including lifelong sensorineural hearing damage and neurological impairment, became fully appreciated, this earned a high priority status as a target for universal vaccination.^{29,643} Primary maternal infection leads to frequent transplacental transmission and is tied to severe disease in newborns.⁶⁵ Viral transmission from primary and recurrent maternal infection both contribute to the overall congenital disease burden in the United States⁶⁹⁵ and other developed countries, with recurrent infection predominating in other areas of the world. In the overall population, transplacental transmission is infrequent, and ranges broadly from roughly 0.3% to 2% of newborns, depending on many factors. Transmission is more frequent in younger women as well as during the third trimester, although transmission during the first or second trimester is associated with greater risk of congenital disease. Placental infection^{122,469} may be much more frequent and may be a barrier to intrauterine transmission, although this area needs more systematic study. Perinatal and postnatal infection of full-term newborns, often acquired from breastfeeding,²³² is of little disease consequence. Premature or immunodeficient infants risk HCMV disease during delivery, from blood transfusion, or from breast milk,²³² and sometimes results in a systemic disease constellation.⁵² Lactating HCMV seropositive mothers commonly shed virus in milk along with HCMV-specific antibody that may neutralize virus, thereby dampening transmission.¹⁷³ Once infected, infants and children shed virus in saliva and urine for months to years and remain an important source of virus infecting parents as well as other childcare providers.⁹⁵ Remarkably low awareness of HCMV in the general population

as well as among physicians⁵³⁶ poses a challenge to efforts in dealing with congenital disease.

HCMV exhibits remarkable genome variation and heterogeneity during natural infection,^{139,216,217,520} a characteristic that has been documented in virus shed by congenitally infected infants.⁵²⁰ The consequences of this variation are presently unknown. Because transmission occurs commonly through contact with bodily secretions and fomites, handwashing is an effective intervention to prevent primary infection in pregnant women.¹¹ Development of a vaccine to prevent congenital HCMV remains an area of unmet medical need and potential promise.⁵⁰

HCMV remains an important etiologic agent of opportunistic infections and disease in immunocompromised hosts, generally emerging in the face of poor T-cell function. Infection in immunocompetent adults is clinically benign, although febrile illness and heterophile-negative infectious mononucleosis may be common.¹³⁶ The T-cell response to HCMV is remarkable. High frequencies of antigen-specific major histocompatibility complex (MHC) class II-restricted CD4 and MHC class I-restricted CD8 T-cell responses develop over the course of life,^{290,644} increasing in frequency with age.⁶⁹¹ T-cell immunity is important for the lifelong suppression of virus replication, as well as for maintaining latency. Helper CD4 and, in particular, cytotoxic CD8 T-cell response levels are recognized as central to the effective host control of viral infection and disease.^{489,530,672,691} HCMV infection and disease predominate during immunosuppressive therapy, particularly in settings of allograft rejection following solid organ transplant (SOT) and allogeneic hematopoietic cell transplant (HCT) recipients, as well as in acquired immunodeficiency disease syndrome (AIDS). Given that settings where this virus causes disease can sometimes be predicted because they result from medical interventions, preemptive therapy and prophylaxis strategies are commonly employed to suppress infection before disease appears.^{190,302} The currently licensed antiviral drugs, ganciclovir/valganciclovir, are used to treat clinically evident disease as well as for prophylaxis and preemptive therapy strategies, with foscarnet and cidofovir as back-up drugs.⁵⁰⁵ Although highly beneficial, these antiviral drugs have been recognized as inadequate in many settings that affect outcomes in transplantation as well as in congenital disease.

General Characteristics

All beta herpesviruses share common characteristics, including appearance in electron micrographs (Fig. 62.1) a prolonged replication cycle in cell culture, species specificity, and a tropism for differentiated hematopoietic and epithelial cell types. Cytomegaloviruses isolated from a mammalian species are most readily propagated in cultured fibroblasts from the homologous host species. During natural infection, HCMV engages epithelial and myeloid (monocyte/macrophage and dendritic) cells, as well as fibroblasts and endothelial cells.⁵²³ HCMV-infected cells develop characteristic cytopathology, exhibiting both nuclear and cytoplasmic inclusions. The latter is associated with a distinct cytoplasmic viral assembly compartment (AC) composed of cellular membranes and organelles that support viral final steps in maturation and release.¹⁴⁴ When propagated in human fibroblasts, HCMV clinical isolates acquire mutations¹⁴¹ in a manner that suggests a process of adaptation.^{139,619} A comparison of laboratory-propagated strain AD169 and wild-type strain Merlin is depicted in Figure 62.1. Mutation of RL13 and UL128 (Table 62.1) occurs rapidly, even after few passages,

suggesting that these membrane impede viral replication in fibroblasts.⁶¹⁹ Although the negative impact of either gene product in fibroblasts remains elusive, pUL128, along with pUL130 and pUL131A (any of which mutates during virus passage in fibroblasts), forms a pentameric envelope complex that contains glycoprotein (g)H and gL and facilitates entry into epithelial and endothelial cells.^{523,539,699} TB40/E is a low passage endothelial tropic strain used for experimental investigations.⁵⁸⁴

Human fibroblasts (e.g., MRC5) are commonly employed for isolation as well as propagation of HCMV, and these cells have been key to understanding how viral gene functions control the various steps in replication (Fig. 62.2). Fibroblasts retain full permissiveness when immortalized with either telomerase or human papillomavirus E6/E7 oncoproteins. Retinal pigment epithelial (e.g., ARPE-19) and astrocytoma (e.g., U373-MG) cancer cell lines are susceptible to HCMV, but other transformed cell lines are typically nonpermissive. Although replication stalls, cytomegaloviruses can enter and proceed through the early stages of the viral replication cycle in many cell types, including cells from other animal species. When exposed to HCMV fibroblasts from nonhomologous animal species such as mouse, attachment, entry, uncoating, and viral IE gene expression proceed (see Fig. 62.2), but viral DNA replication fails to occur. Studies on HCMV infection of human fibroblasts suggest roles for virus-encoded cell death suppressors³⁷⁷ as well as other viral gene controlling early steps⁵⁶⁸ as critical determinants to overcome the species barrier.

HCMV DNA or antigens in peripheral blood (PB) are important and specific markers of infection and disease,²⁰⁷ particularly in at-risk immunocompromised transplant recipients.^{190,302} Two common methods, quantitative DNA PCR amplification, which can be applied to whole blood, tissue, and body fluids, and detection of viral antigen, applied to PB cells as an antigenemia assay, are complementary methods for diagnosis of infection.²⁰⁷ Viral antigens and nucleic acids may also be assessed directly in affected tissues. These indicators of active HCMV infection are used in combination with clinical diagnosis to guide antiviral therapy.⁵⁰⁵ Primary infection in immunologically normal children or adults, including pregnant women and newborns, is readily diagnosed by detection of virus or viral DNA in urine or saliva. These body fluids may contain virus continuously for months to years, and virus reappears in these fluids sporadically during life. Serologic assessment of HCMV-specific antibodies is a more common means of diagnosing previous infection, and is a highly specific and accurate indicator of long-term infection. Natural latency of HCMV occurs in blood marrow (BM)-derived hematopoietic cells⁵⁸⁰ where viral DNA is present at very low frequencies (10^{-5}) and low copy number (2 to 10 genome equivalents per cell)^{581,589} and is associated with limited viral transcription.^{47,515} The precise status and regulation of HCMV during life-long infection remains a topic of active investigation.⁵⁸¹

Viral Strains and Cell Tropism

HCMV strains accumulate deletion and point mutations when propagated in cell culture.^{139,141,619} Replication and release of progeny virus improves with adaptation through repeated passage on fibroblasts, while, at the same time, ability to infect endothelial and epithelial cells is compromised.^{139,523,619} As a result, laboratory strains such as AD169¹¹² and Towne^{167,417} carry substantive mutations and rearrangements compared to

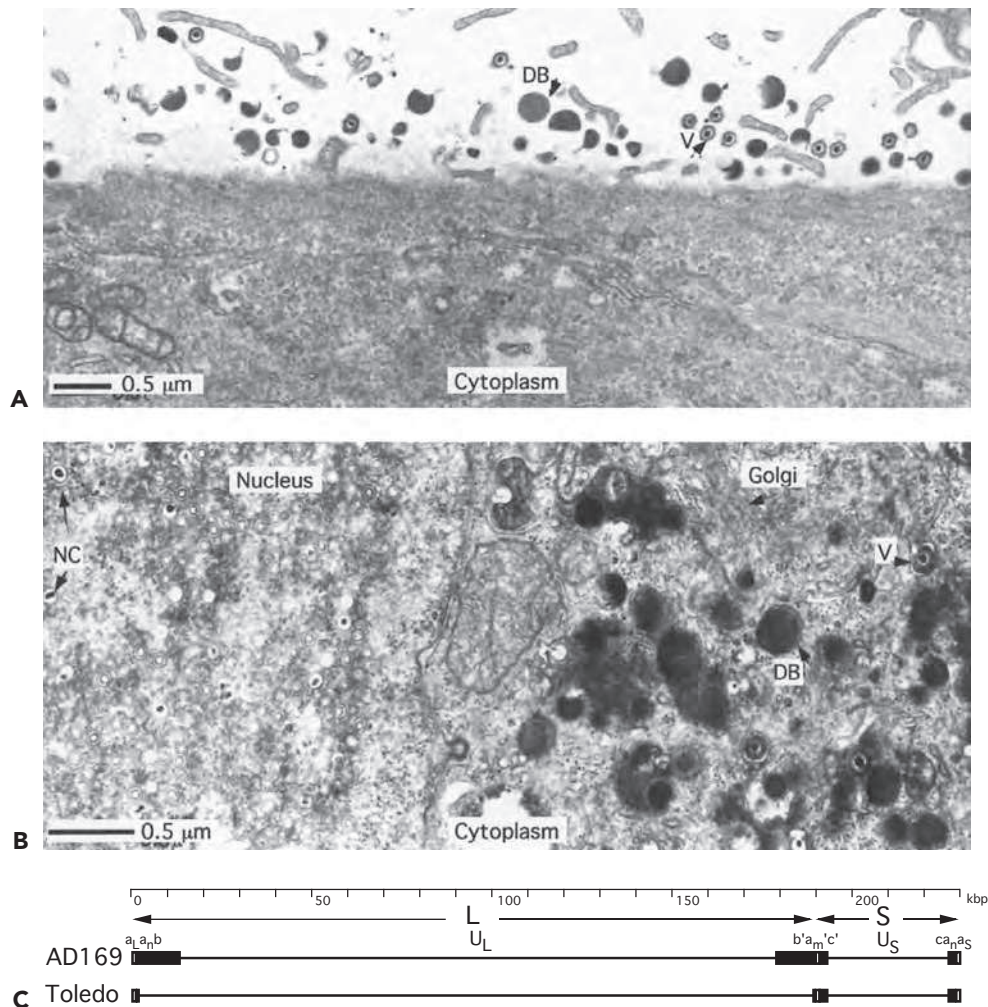

FIGURE 62.1. Virus particles, replication, and genome structure. **A:** Surface of a cell onto which virions (V) and dense bodies (DB) of human cytomegalovirus (HCMV) (Towne strain) have attached. This illustrates the size and approximate ratio of these two types of particle in a virus preparation and the ability of both to attach to the cell surface. **B:** Productively infected cell with nucleocapsids (NC) in the nucleus and maturing virus (V) and dense bodies (DB) in the enlarged Golgi region of the cytoplasm, which forms the characteristic cytoplasmic inclusion of HCMV. Many capsids lacking a dense core of nucleic acid can be observed in the nucleus where, along with nucleocapsids, they form a characteristic inclusion within a kidney-shaped nucleus that is displaced by a cytoplasmic inclusion, a compartment where final steps in maturation occur (giving an “owl’s eye” appearance to cells).²⁴⁷ Envelopment of nucleocapsids (and capsids) occurs at the inner nuclear membrane, where thickened patches of modified membrane develop, followed by final envelopment in the cytoplasm. Dense body envelopment occurs exclusively at cytoplasmic membranes. The bar represents 0.5 μm . **C:** HCMV genome structure. The top line is a size scale in kbp (kilobase pairs = 1000 bp). The second line depicts the L and S components of the genome by arrows. The complete sequenced AD169varUK strain genome structure^{112,159} is shown on the third line with unique sequences (thin lines) flanked by inverted repeats (boxed areas). The genome structure of a low passage strain Merlin as an example of a wild strain is depicted on the fourth line.^{106,159} Note that the region shown as *b* sequence repeat on the left end of the L component in the AD169 strain is retained in wild strains as unique sequence; the *b* sequence repeat on the right is replaced by additional unique (U_L) sequence. The lettering above the genome depicts the following features. The L-terminal *a* sequence repeat (a_L), zero to several (*n*) additional copies of the *a* sequence (a_n), L-terminal *b* sequence repeat of the L component, the unique sequences of the L component (U_L), the L-S junction *b* sequence inverted repeat (b'), one to several (*m*) additional copies of the *a* sequence inverted repeats at the L-S junction (a'_m), the L-S junction *c* sequence inverted repeat (c'), the unique sequences of the S component (U_S), S-terminal *c* sequence repeat, and the S-terminal *a* sequence repeat (a_S) with a variable number of additional copies of the *a* sequence (a_n). The *b* and *b'* repeats are also called TRL and IRL, respectively; and *c'* and *c* repeats are also called IRS and TRS, respectively. In different strains of CMV, including clinical isolates, the *a* sequence ranges in size from 700 to 900 bp.

TABLE 62.1 Summary Information on HCMV Gene Productsⁱ (Continued)

HCMV gene ^{a,b}	HHV-6/T HHV-7 ^a	HCMV gene family/expression ^c	Function/comments ^d
UL72	U45	(core) DURP family; tegument, LL	DURP, Deoxyuridine triphosphatase homolog (enzymatically inactive) ⁹⁸
UL73	U46	(core) Virion envelope gp, L	gN, complexes with gM to support envelopment; high sequence variability ^{358,478,479}
UL74	U47	Virion envelope gp,	gO, enhances gH:gL delivery and release of virions ^{271,540,679}
UL74A	UL47A	Putative virion gp (also called UL73.5)	Multiple spliced variants ^{204,556}
UL75	U48	(core) Virion envelope gp, TL	gH, complexed with gL; gH-gL associates with gO or UL128-UL131A; role in entry ^{131,680}
UL76	U49	(core) Virion-associated protein	Translational impact on UL77 ²⁶³
UL77	U50	(core) DNA encapsidation, DE	CVC1, putative capsid vertex-specific component 1
UL78	U51	GPCR family; virion envelope gp, DE	Putative chemokine receptor ³⁹¹
UL79	U52	(betagamma)	L gene transactivator ^{264,471}
UL80	U53	(core), L	PR-AP precursor, maturational protease (N terminus) and capsid assembly (scaffold) protein (C terminus) ^{80,730}
UL80.5	U53.5	(core), L	AP precursor, capsid assembly (scaffold) protein ^{80,730}
LUNA			Latency-associated ^{46,511}
UL82	U54	DURP family; tegument pp, L	pp71, VTA, upper matrix protein; ND10 localized; degrades Daxx and Rb, relieving repression ^{258,430}
UL83		DURP family; major tegument pp, LL	pp65, lower matrix protein; suppresses interferon response ³⁷¹
UL84	U55	DURP family; DNA synthesis, DE	Initiation of DNA synthesis; binds IE2, UL112-113 and PPS ^{21,277,295,443}
UL85	U56	(core) Capsid, LL	TRI2, capsid triplex component 2; interacts with TRI1/UL46; minor capsid protein ^{80,113,669}
UL86	U57	(core) Capsid, L	MCP, major capsid protein; component of hexons and pentons ^{80,113,669}
UL87	U58	(betagamma)	L gene transactivator ²⁶⁴
UL88	U59	(betagamma) Tegument	Putative cytoplasmic egress
UL89x1	U66 x 1	(core) DNA encapsidation, LL	TER1, terminase subunit 1 ATPase; inhibition by antiviral compounds ^{425,658}
UL89x2	U66 x 2		
UL90			
UL91	U62	(betagamma), L	
UL92	U63	(betagamma), L	
UL93	U64	(core) DNA encapsidation, L	CVC2, putative capsid vertex-specific component 2
UL94	U65	(core) Tegument, TL	Secondary envelopment in association with pp28 ^{344,475}
UL95	U67	(betagamma), DE	L gene transactivator ²⁶⁴
UL96	U68	Tegument, DE	Stabilization of nucleocapsids during nuclear-cytoplasmic translocation ⁶⁵²
UL97	U69	(core) Viral serine-threonine protein kinase; tegument, DE	VPK, viral protein kinase, phosphorylates ganciclovir; mimics cdc2/CDK1; target of maribavir antiviral; phosphorylates many viral and cellular proteins ^{254,330,494}
UL98	U70	(core), DE	NUC, deoxyribonuclease ³⁰⁹
UL99	U71	(core) Myristylated tegument pp, TL	pp28, secondary envelopment; multimerization ^{570,571}
UL100	U72	(core) 8TM virion envelope gp	gM, complexes with gN; role in envelopment ^{80,307,308}
UL102	U74	(core) DNA synthesis, DE	HP3, DNA helicase-primase subunit ^{21,443}
UL103	U75	(core) Tegument, L	VEP, Virion and dense body egress protein; Enhances release ¹⁶
UL104	U76	(core) DNA encapsidation, DE	PORT, portal protein; DNA encapsidation ¹⁵⁷
UL105	U77	(core) DNA synthesis, DE	HP1, DNA helicase-primase subunit; helicase homology ^{21,443}
(RNA5.0)		Noncoding RNA, IE	Stable intron ³¹¹
UL111A		L	vIL-10, viral interleukin 10 and latency-associated (LA) vIL-10 ^{36,587}
UL112–113	U79	DNA synthesis accessory, DE	Multiple spliced variants; transcriptional activation, orchestration of DNA synthesis ²⁹⁵
UL114	U81	(core) DNA synthesis accessory, DE	UNG, Uracil-DNA glycosylase; role in excision of uracil from DNA and control of DNA synthesis ^{496,503,633}
UL115	U82	(core) Virion envelope gp, TL	gL, complexed with gH; gH-gL associates with gO or UL128-UL131A in cell tropism; role in entry ^{74,131,680}

TABLE 62.1 Summary Information on HCMV Gene Productsⁱ (Continued)

HCMV gene ^{a,b}	HHV-6/T HHV-7 ^a	HCMV gene family/expression ^c	Function/comments ^d
UL116 UL117	<i>U84</i>	Putative membrane gp, LL L	Enhances replication compartment formation; impairs cell DNA synthesis ⁵⁰⁰
UL118-UL119 UL120 UL121	<i>U85^d</i>	IgG Fc-binding virion envelope gp, DE UL120 family; putative membrane gp, L UL120 family; putative membrane gp, L	gp68, binds IgG Fc, related to OX-2, ^{35,609}
UL122	<i>U86</i>	IE (alternatively spliced with UL123) (L60, LL, and L40, TL)	IE2, principle transactivator of host cell transcriptional machinery; sequence-specific DNA-binding repressor; cell cycle impact ^{552,631}
UL123	<i>U90^e</i>	IE (major, alternatively spliced with UL122)	IE1, Major IE protein; enhances activation by IE2; indirect enhancement of transcription; binds HDACs; disrupts PML bodies/ND10 ^{576,654}

ⁱCoordinated with HCMV genome map (Figure 62.3).

^aCommonly annotated open-reading frames (ORFs) of human cytomegalovirus (HCMV), together with selected ORFs conserved in roseoloviruses, human herpesvirus (HHV)-6 (A or B), and HHV-7. Additional references⁴⁰⁰ and functional dissection by mutagenesis^{167,727} showing replication better than wild-type (*underlined normal type*), little difference from wild-type (*normal type*), or one of two broad growth deficient phenotypes: failure to replicate (*bold black²*), or poor replication (*bold gray³*), when viruses are assayed in fibroblasts. ORFs that impact levels of replication in a cell type-specific manner are underlined.

^bBeta herpesvirus-common genes are in italics, and include 40 herpesvirus core functions, labeled "core" as well as genes conserved in beta- and gamma herpesviruses, labeled "betagamma." Gene family, characteristics, and functional information are provided for HCMV, where a blank indicates the absence of information.

^cGene family (see Fig. 62.2) and expression class based on transcript accumulation (IE, immediate early; DE, delayed early; LL, leaky late; TL, true late; L, late, not further studied).

^dFunctional information is based on information from studies on HCMV, murine cytomegalovirus (MCMV), and other herpesviruses. References limited to recent publications focused on gene function in HCMV.

^ePositional homolog lacking sequence similarity.

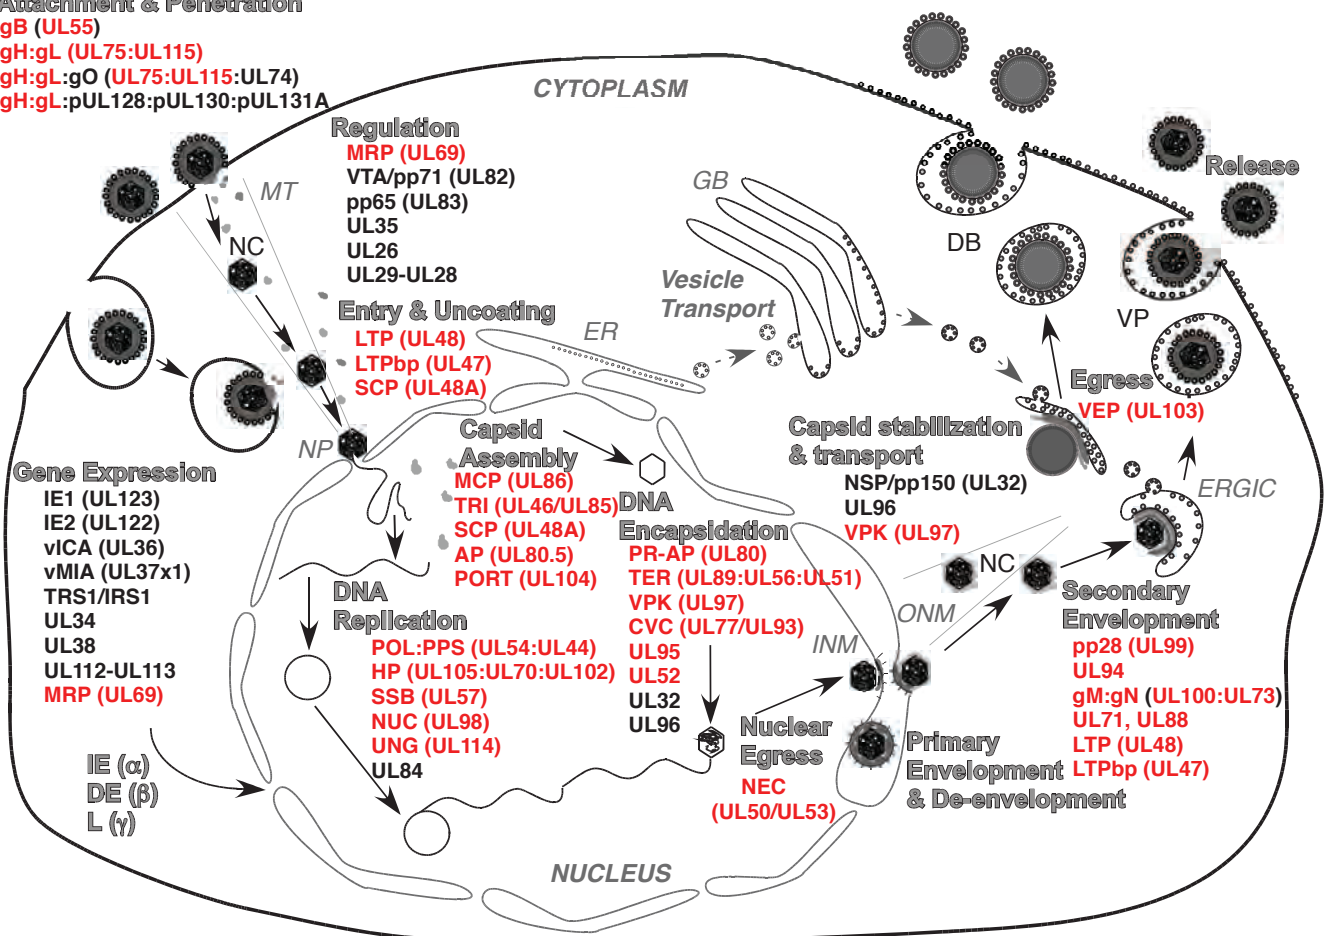

Attachment & Penetration**gB (UL55)****gH:gL (UL75:UL115)****gH:gL:gO (UL75:UL115:UL74)****gH:gL:pUL128:pUL130:pUL131A**

FIGURE 62.2. Summary of the human cytomegalovirus (HCMV) replication pathway. Major steps in productive replication are indicated in *large gray font with outline*, black arrows indicate the progression of steps and viral functions (see Table 62.1 for summary descriptions). Individual gene products listed under each step are identified by provisional abbreviated names^{399,400} as either herpesvirus core (red text) or beta herpesvirus conserved (black text). Viral attachment and penetration occur either via direct fusion at the cell surface (fibroblasts), dependent on gB, gH:gL and gH:gL:gO, or via endocytosis into other cell types (endothelial and epithelial cells) where the pentameric complex, gH:gL:p128:p130:p131A, also facilitates entry (see text). In addition to the interferon (IFN)-like activation of cells by the process of attachment and penetration, input virion tegument proteins (UL69/MRP, pp71/VTA, pp65, UL35, UL26, and UL29-UL28) regulate cellular pathways. NC-associated UL47, UL48, and smallest capsid protein (SCP) are predicted to facilitate the final steps in entry and uncoating that deliver input nucleocapsid (NC) via microtubules (MT) to nuclear pore (NP) complexes where the viral genome is released into the nucleus. Transcriptional regulation of viral and host cell gene expression is mediated by IE genes (IE1, IE2) or DE genes (UL34, UL35, UL112-UL113, and UL69); cell death suppression is mediated by IE gene products vICA and vMIA, and other regulatory processes are facilitated by UL34, UL38, and UL112-UL113 proteins. DNA replication depends on core proteins (POL:PPS, HP, SSB, NUC, and UNG) as well as one beta herpesvirus-specific protein (UL84 gene product) that facilitates initiation of DNA synthesis. Capsids assemble from MCP, TRI, SCP, PORT, and AP. Preformed capsids process PR-AP (UL80) and AP as viral DNA is encapsidated by the TER complex (UL89, UL56, UL51) through a PORT (UL104) pentamer, followed by predicted addition of the CVC complex (UL77, UL93) onto NC pentamers, with UL95, UL52, UL32, and UL96 added for NC stabilization. Nuclear egress of the NC is mediated by the NEC (UL50, UL53). Following primary envelopment at the inner nuclear membrane (INM), and de-envelopment at the outer nuclear membrane (ONM), capsid stabilization is ensured by the function of NSP/pp150 (UL32) and UL96, with nuclear egress and transport facilitated by VPK (UL97). Glycoproteins incorporated into the envelope are synthesized in the endoplasmic reticulum (ER), glycosylated in the Golgi body (GB), and delivered by vesicle transport (dashed gray arrow) to join NC at sites of secondary envelopment on ER Golgi intermediate compartment (ERGIC). Secondary envelopment requires UL99, UL94, gM/UL100:gN/UL73, UL71, UL88, UL47, and UL48, acting together with VPK. Following the acquisition of an envelope, virus particle (VP) as well as capsid-less dense body (DB) egress is facilitated by VEP/UL103 for release into the extracellular space.

a wild-type HCMV prototype^{106,139,141,149,150} (see Fig. 62.1). Adapted strains replicate very well in fibroblasts but poorly on cultured macrophages, dendritic cells, endothelial cells, or epithelial cells. In addition to adaptive mutations, it has become clear that viral stocks often consist of multiple strain variants and that laboratory adapted viral strains in common use around the world differ markedly.^{77,138} Serial propagation of common laboratory strains results in stable strain variants^{77,138} that exhibit unique biological properties such as upregulation of cell cyclin-dependent kinases resulting in pseudomitosis²⁴⁶ as well as other alterations in host cell response to infection.³⁹⁹ Comparison of viral genomes from low passage or even non-propagated wild-type strains in clinical samples facilitated current estimate of HCMV genome coding capacity^{106,139,141,149,150} and led to the derivation of bacmid clones of low-passage strains for experimental use.^{584,619} Recent deep DNA sequencing has revealed considerable heterogeneity as well as the presence of multiple viral strains within clinical samples.^{139,216,217,520} Deep sequencing approaches have also facilitated assembly of a high-resolution transcriptome²⁰⁴ and unveiled a level of messenger RNA (mRNA) greater than previously appreciated for this virus, two features that still need to be integrated into the growing understanding of HCMV biology.

The AD169 and Towne stocks distributed by the American Type Culture Collection (ATCC) include a mixture of genomes. Replication-competent variants with substantive genome rearrangements and deletions have been independently propagated from various AD169 and Towne preparations.^{77,138} Cell tropism factors have come from such studies⁵³⁸ and have opened the way to a more complete understanding of HCMV biology. Two examples include the role that virion envelope glycoprotein gpRL13 plays in suppressing replication in fibroblasts⁶¹⁹ and the role that the pentameric complex composed of gH:gL:pUL128:pUL130:pUL131A plays in facilitating entry into epithelial and endothelial cells.^{523,539,699}

CLASSIFICATION

The starting point for classification of cytomegaloviruses infecting humans and other animals is comparative biology, physicochemical characteristics, and virion morphology. Over the last 20 years, genome sequence analysis has eclipsed other approaches in viral taxonomy.^{146,465} Cytomegaloviruses have been isolated from a wide variety of mammalian species, including dogs, horses, bats, cows and pigs, although many have not been fully characterized.²⁴⁷ Beta herpesviruses, in general, are associated with universal infection in their natural host species. Four groups of beta herpesviruses have been officially recognized⁴⁶⁵: (1) known human and primate cytomegaloviruses; (2) muromegaloviruses, including MCMV and rat CMV; (3) beta herpesvirus causing roseola (human herpesvirus type 6B [HHV-6B]) as well as two close relatives (HHV-6A and HHV-7); and, (4) proboscivirus, endotheliotropic elephant herpesvirus. Other beta herpesviruses, such as guinea pig CMV and porcine CMV, as well as Tupaia herpesvirus, remain unclassified.⁴⁶⁵ The beta herpesvirus subfamily exhibits a greater level of evolutionarily and genetic divergence than either alpha herpesviruses or gamma herpesviruses. This situation poses a challenge to investigators trying to understand virus biology by studying these surrogate animal models. MCMV and HCMV exhibit many common biological

attributes in pathogenesis, immunomodulation, and latency, but appear to achieve these ends via evolutionarily divergent mechanisms and gene products.^{348,394,398,401,405} RhCMV has been championed as more HCMV-like^{41,490} and has raised interest in cytomegaloviruses as vaccine vectors in the face of preexisting immunity.²³⁷ Importantly, nonhuman primate surrogates have obvious limitations in that the host animals are limited, plus RhCMV is evolutionarily divergent. There remains a need for intensive investigation of natural HCMV infection and immunity, as well as for further optimization of humanized small animal models^{593,675} to facilitate direct study of HCMV.

The HCMV genome is the largest of any characterized herpesvirus, at 236,000 bp (HCMV), with an annotated capacity to encode at least 167 protein-coding gene products¹³⁹ (Table 62.1 and Fig. 62.3), with extensive alternate mRNA splicing in certain regions²⁰⁴ (Table 62.2), plus noncoding RNAs as well as micro (mi)RNAs^{156,182,223,623} (Fig. 62.3). Other cytomegaloviruses exhibit a level of genome complexity similar to HCMV, whereas roseoloviruses have smaller genomes encoding approximately 85 genes. Alternative annotation methods^{82,473} and sensitive experimental detection^{156,182,204,223,623} have complemented each other in the annotation of HCMV genome coding potential.

Neither human roseoloviruses nor nonhuman cytomegaloviruses share significant DNA sequence identity with HCMV. Evolutionary relationships between beta herpesviruses emerge from comparisons of predicted protein coding sequences and appear to follow relationships of host animal species consistent with longstanding pathogen–host co-evolution.⁴⁰⁵ Independent coevolution belies the biological similarity of cytomegaloviruses infecting diverse mammalian hosts. Only 75 of the estimated 167 HCMV protein-coding genes are conserved across this group, including 40 core herpesvirus and seven (UL49, UL79, UL87, UL88, UL91, UL92, and UL95) betagamma conserved genes (Table 62.1). On one end of this spectrum, 163 of the predicted 168 chimpanzee CMV proteins are homologous and colinear with HCMV.¹⁴⁹ Only about 111 RhCMV genes are homologous to HCMV genes⁵³¹; in guinea pig CMV, relatedness falls off to 84 homologs,²⁸² and in MCMV or rat CMV genomes 75 sequence homologs are present.²⁸² These comparisons have consistently shown that beta herpesviruses are remarkably diverse in genetic composition. As information accumulates, it appears that the immune modulators in these viruses evolved to target a common set of host immune control pathways from evolutionarily distinct origins and using distinct mechanisms. Because of the smaller number of total genes, a high proportion of human roseoloviruses genes have homologs in HCMV,¹⁴⁹ and these overlap with the genes retained in all animal cytomegaloviruses. With few exceptions, both beta herpesvirus-conserved genes and herpesvirus core genes are concentrated between UL23 to UL123, with additional US22 family members flanking this region. Many genes within as well as outside this central region are involved in modulation of the host response to virus infection. Genes near the ends of viral genomes represent the most recent evolutionary acquisitions and provide evidence of evolutionary adaptation to host defense pathways.⁴⁰⁵

Like all herpesviruses, beta herpesviruses have linear DNA genomes with direct terminal repeats containing the *cis*-acting signals (*pac1* and *pac2*) recognized by the encapsidation machinery to initiate packaging and direct genome cleavage.⁷⁰² HCMV and guinea pig CMV have large (approaching 1,000 bp) terminal repeats, whereas MCMVs has a small (<50 bp)

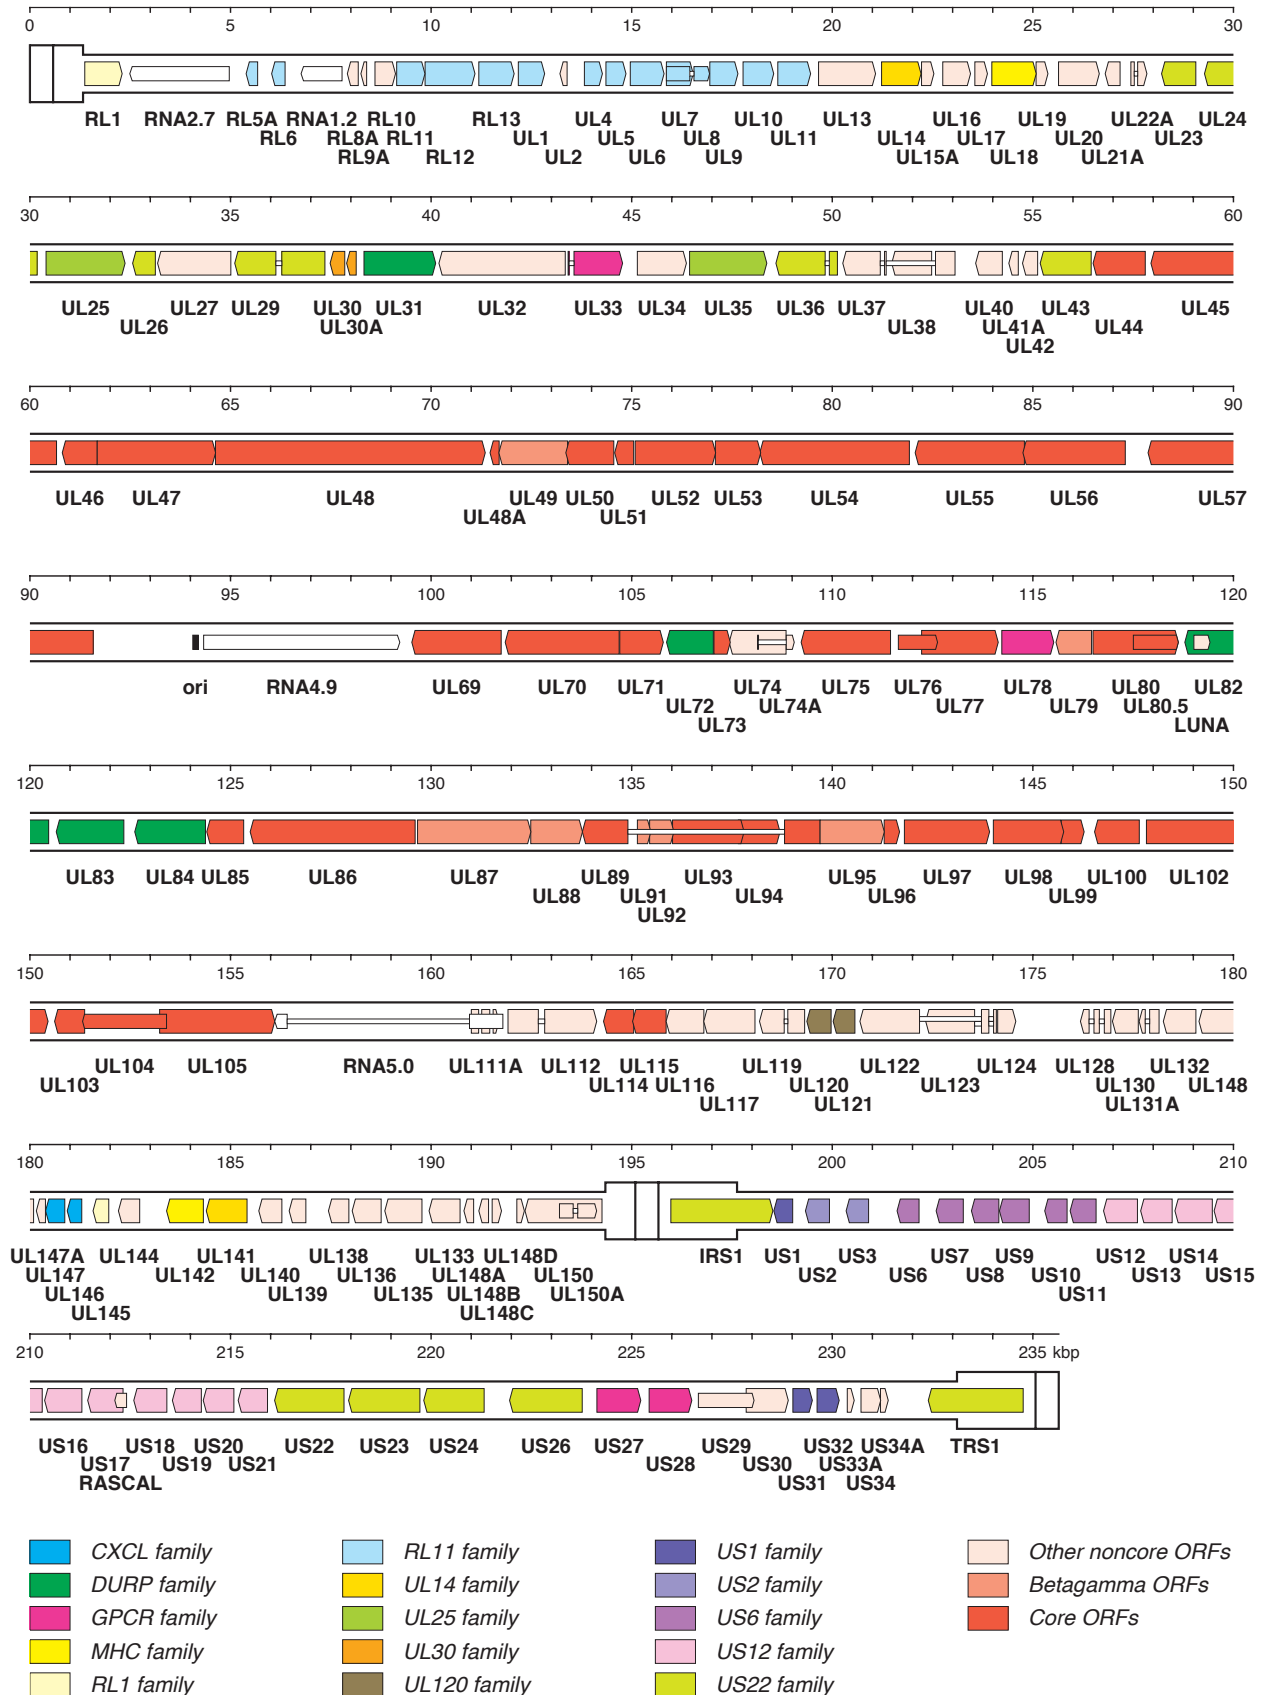

FIGURE 62.3. Genetic organization and content of wild-type human cytomegalovirus HCMV, based on an updated interpretation⁶⁶⁸ of consensus sequences.^{145,418} The inverted repeats TRL/IRL and TRS/IRS including *a* sequences are shown in a thicker format than U_L and U_S. Protein-coding regions are indicated by *arrows*, and gene names are listed below. Introns are shown as *narrow white bars*. Genes corresponding to those in TR_L/IR_L and TR_S/IR_S of strain AD169 are given their full nomenclature, but UL and US prefixes have been omitted from UL1-UL150 and US1-US34A, respectively. Herpesvirus core genes and gene families are color-coded as indicated in the legend. White genes are unique.

TABLE 62.2 Summary Information on HCMV miRNAs

miRNA ^{a,b}	Sequence ^c	Abundance ^d	Function/comments ^e
miR-UL22A-1-5p	TAAC TAGCCTTCCCGTGAGA	0.041	Detected in cells infected with HCMV AD169 ²²¹ and clinical isolates AF2380 U8795, ⁶²⁶ but not Towne ⁶²³

miR-US33as-1-3p	CCCACGGTCCGGGCACAATCA	0.002	

^amiRNAs were identified by a combination of small RNA cloning and sequencing,^{168,473} comparison of HCMV and chimpanzee genomes,²²¹ and deep sequencing of small RNAs⁶²³ from infected fibroblasts. miR-UL23-5p, miR-UL23-3p, and miR-US24¹⁶⁸ were renamed miR-UL22A-5p, miR-UL22A-3p, and miR-US25-1, respectively.¹⁶¹

^bmiRNAs are named for the viral open-reading frame (ORF) with which they overlap; or, if they reside between ORFs, they are named for the nearest upstream annotated ORF encoded on the same strand of the viral genome. ORF designations are followed by a number to distinguish multiple miRNAs in the same ORF location, and the two arms processed from a common pri-miR hairpin are distinguished by 5p versus 3p.

^cMost abundant form in fibroblasts at 72 hpi with the HCMV Towne strain.⁶²³

^dRelative abundance at 72 hpi is based on a calculation from deep sequencing results reported in⁶²³; that is, the number of sequence reads for each miRNA divided by the combined sequence reads for all miRNAs (except miR-UL70-1–5p, which was not detected, ND).

^eTarget identification/validation methods included: Luciferase reporter assay or ectopic expression; Protein assay in infected cells; Virus mutated for miRNA; Virus mutated for target site; RISC immunoprecipitation.

terminal repeat that suffices for genome cleavage and packaging.³⁸⁵ Similar to human alpha herpesviruses, primate cytomegaloviruses have an internal inverted copy of the *a* sequence terminal repeat that supports homologous recombination-driven genome rearrangement during replication.⁴²⁴ As a result, HCMV and chimpanzee CMV have class E genomes (Fig. 62.1; see Chapter 59, Herpesviridae) generating four isomers that appear to package with equal efficiency, whereas RhCMV, roseoloviruses, muromegalovirus, and guinea pig CMV have linear DNA genomes that do not rearrange at all (referred to as class A genomes). Genome isomerization is dispensable for HCMV replication⁵⁵⁵ as it is in other herpesviruses. The importance of genome isomerization in the biology of any herpesviruses remains a complete mystery.

Consistent with the conserved set of proteins and despite variation in genome structure and existence of genome isomers, all beta herpesviruses, follow a replication pathway (Fig. 62.2) from DNA replication^{21,424} through capsid formation and DNA encapsidation,^{84,99} nuclear egress, and final virion maturation steps^{80,653} common to all herpesviruses.

VIRION STRUCTURE

HCMV has a structure characteristic of all herpesviruses,^{80,84,99} with a DNA core inside of a highly stable icosahedral capsid made up of 162 capsomeres surrounded by an envelope derived from host cell membrane containing viral glycoproteins to

control attachment and entry into cells. Herpesviruses have a particularly thick tegument (or matrix) layer of virus-encoded proteins between the capsid and envelope. Cryoelectron microscopy in combination with computer-assisted tomographic image reconstruction (cryoEM or cryoET)^{84,342} has provided accurate nucleocapsid dimensions as well as other structural details of the 200 to 230 nm virion particle. HCMV has a 130-nm icosahedral nucleocapsid, somewhat larger than other herpesviruses, that accommodates a large genome. Overall, the virion is the most structurally complex of the characterized herpesviruses. Whether observed in thin sections of infected cells (Fig. 62.1) or as purified virion and dense body preparations resolved either by transmission EM or cryoEM, virus particles have a pleomorphic appearance with a voluminous tegument layer that is asymmetric.⁷²⁹

HCMV capsids are composed of four herpesvirus core proteins, major capsid protein (MCP, the UL86 gene product) comprising hexons and most pentons, triplexes composed of two subunits, triplex subunit 1 (TRI1, the UL46 gene product or minor capsid protein) and triplex subunit 2 (TRI2, the UL85 gene product or minor capsid protein binding protein), and the smallest capsid protein (SCP, the UL48A gene product). Unlike the situation in HSV-1 where SCP is dispensable, all capsid proteins are essential for HCMV replication.^{72,80,315} By analogy with HSV-1,^{84,99} one specialized penton composed of the portal protein (PORT, the UL104 gene product) acts as a channel for both encapsidation and release of viral DNA together with two principal subunits of the terminase, subunit 1 (TER1, the UL89 gene product) and subunit 2 (TER2, the UL56 gene product). A capsid vertex-capping (CVC) complex composed of UL77 and UL93 proteins decorates all pentons¹³³ and the proteins encoded by UL51 and UL52 likely provide stability. Inside the HCMV nucleocapsid is a ~236-kb linear DNA genome together with two virion (v) RNAs, ~300 nucleotide vRNA-1, and ~500 nucleotide vRNA-2, embedded as an RNA–DNA hybrid in an essential region the lytic origin of DNA synthesis (*oriLyt*).^{21,443} The nucleocapsid is enclosed in a tegument (or matrix) composed of at least 32 virus-encoded proteins, many of which are phosphorylated. Small amounts of cytoplasmic proteins⁶⁸¹ as well as RNAs⁶⁵⁷ are captured into mature virus particles, likely passively. The tegument is surrounded by a lipid bilayer envelope that is derived from the ER–Golgi intermediate compartment (ERGIC) or recycling endosomal compartment modified by insertion of approximately 23 virus-encoded glycoproteins. Five envelope glycoproteins (gB, gH:gL, gM:gN) provide essential replication functions and are targets of neutralizing antibody. In total, the virion is composed of at least 66 virus-encoded proteins that play diverse roles during infection (Table 62.1 and Fig. 62.2). Many virion proteins mediate and modulate entry and egress, influence cell tropism, and interface with the host response to infection. Although additional minor tegument and envelope components are likely to be recognized given the large coding capacity and truly extensive mRNA splicing,²⁰⁴ HCMV has the most complex of herpesvirus virions.

Purified HCMV preparations contain an abundance of noninfectious defective particles in addition to virions. Infected cells release both capsidless and capsid-containing particles such that defective particles constitute roughly 99 percent of material in highly purified virus preparations. The most carefully purified HCMV preparations exhibit particle-to-PFU (particle forming unit) ratios exceeding 100, and high

multiplicity propagation can result in particle-to-PFU ratios approaching 10,000 due to enrichment of defective interfering particles.⁶³⁰ Capsidless dense bodies constitute approximately 50% of particles collected from culture supernatants (Fig. 62.1). Dense body formation depends upon pp65 tegument protein and takes place in the same cytoplasmic AC using the same cytoplasmic membranes as virions (Fig. 62.2). Noninfectious enveloped particles (NIEPs) form when genomeless capsids mature through the cytoplasm and are released.²¹⁰ Even carefully executed studies seeking to identify virion and dense body structural components^{657,681} have encountered heterogeneity, cross-contamination, and difficulty in removing host contaminants even though these virus particles have been enriched by differential sedimentation. Furthermore, virus strain-to-strain variability may also influence protein composition of virus particles (Plachter, personal communication). An abundance of DNA-containing defective particles are produced during infection but cannot be distinguished or separated from infectious virions by physicochemical properties.

Capsid

CryoEM analyses³⁴² revealed unique characteristics of the inner capsid surface of HCMV and simian CMV nucleocapsids, in addition to the larger volume to accommodate these large genomes. The icosahedral nucleocapsid exhibits icosahedral T = 16 symmetry assembled from 162 capsomeres like all herpesviruses and the HK97 group of tailed bacteriophages.^{84,99} One hundred fifty hexons, each consisting of six molecules of MCP, make up the triangular faces of the capsid. Eleven pentons, each consisting of five molecules of MCP together, plus one specialized penton made of PORT complete the capsid wall. Hexons and pentons together form the bulk of the 15-nm-thick capsid walls. Therefore, like all herpesviruses,^{84,99} the HCMV capsid comprises 955 molecules of MCP, 12 molecules of PORT, 320 copies of a 2:1 complex consisting of TR2 and TR1 making contact with three capsomers just above the capsid floor, and 900 molecules of SCP, forming six member rings on MCP at hexon tips. The importance of UL77 and UL93 as a CVC complex or the precise role of UL51 and UL52 in nucleocapsid stabilization, have not yet been resolved in structural studies. The organized layer of material on the outer surface of the capsid has been ascribed to one of the major tegument proteins, pp150,⁷²⁹ a structural detail that is unique to HCMV.

Based on studies with HSV-1, an HCMV procapsid shell is likely formed when MCP is translated and imported into the nucleus together with scaffold subunits comprised of assembly protein (AP, UL80.5 gene product) and maturational protease (PR), a PR–AP fusion protein (the UL80 gene product).²¹⁰ After chaperoning subunits to the nucleus where maturation proceeds, the scaffold is replaced as viral DNA is packaged by encapsidation machinery. The capsid assembly process is also common to other herpesviruses^{84,99} and yields three distinct nuclear capsid forms, termed A, B, and C capsids. C capsids represent DNA-containing nucleocapsids that appear to be in the process of maturing; whereas, A and B capsids represent aberrant particles that appear to have failed to complete encapsidation. Viral DNA is arranged in three-dimensional hexagonally packed arrays within the interior of the nucleocapsid together with polyamines and *oriLyt* RNA but without additional virus or host proteins. Some HCMV B capsids complete maturation to become NIEPs. In addition, B capsids accumulate when

maturation is blocked, either using HCMV-specific encapsidation inhibitors,^{158,215} by inhibiting expression of the PR-AP⁷³⁰ or by employing other viral mutants that fail to encapsidate viral DNA.^{73,80} Therefore, there is strong evidence that viral DNA encapsidation drives the generation of C capsids (nucleocapsids) and that these translocate to the cytoplasmic AC where maturation continues and final envelopment takes place.

Tegument

The 32 known tegument proteins (Table 62.1) carry out diverse activities, from conditioning the host cell at the beginning of infection to orchestrating the final stages of virion assembly. They are added to the maturing nucleocapsid in sequential layers, beginning in the nucleus and continuing in the cytoplasmic AC. At the start of infection, these proteins, located entirely within the virion between the nucleocapsid and the lipid bilayer envelope, direct nucleocapsid translocation on microtubules to nuclear pore complexes, delivering the viral genome to the nucleus while also overtaking the host cell machinery (Fig. 62.2). During the final stages of maturation, tegument proteins control nucleocapsid stability, trafficking, and envelopment from the nucleus through to final steps in egress (Fig. 62.2). Many tegument proteins are conserved across herpesviruses. The small amounts of viral and cellular RNAs as well as host proteins that appear to be passively acquired during envelopment reside in the tegument. Most tegument proteins are phosphorylated and many are highly immunogenic.^{80,262}

The most abundant tegument protein in virions is pp65 (lower matrix protein, UL83 gene product). This protein is the major constituent of capsidless dense bodies and is acquired during envelopment in the AC. Despite its abundance and potential importance during natural infection in humans, UL83 is dispensable for replication in cultured cells.⁵⁶⁴ pp65 is highly immunogenic and has proven very useful for monitoring virus-specific immunity in the population because it is a target of MHC class I-restricted CD8 and MHC class II CD4 T-cell responses.⁶⁴⁴ This tegument protein is also the most abundant viral protein in virus-infected cells and may be transferred to neutrophils that come into contact with virus-infected cells during natural infection. Detection of pp65 in PB neutrophils has been the basis of the antigenemia diagnostic assay.³³⁶ Immediately following viral entry, pp65 localizes to the nucleus of infected cells where it has an immunomodulatory role dampening the interferon-like cellular response to infection.²⁶² Late in infection, pp65 is associated with the AC where virion and dense body envelopment occur.

The HCMV UL32, UL48, and UL82 genes encode abundant tegument proteins that play crucial roles during infection. The virion transactivator (VTA) pp71 (upper matrix protein, UL82 gene product), a sequence homolog of UL83, localizes to the nucleus following entry and recruits cellular transcription machinery to activate immediate early (IE) gene transcription.^{472,631} The pp150 (large matrix phosphoprotein, UL32 gene product) is capsid-proximal in virions⁷²⁹ and plays an essential role sustaining stability of maturing nucleocapsids during translocation from the nucleus to the cytoplasmic AC.^{651,653} This phosphoprotein is recognized by more than 80% of HCMV-seropositive sera and is also an important target of cellular immunity. The largest tegument protein (LTP, UL48 gene product) is capsid proximal,⁷²⁹ and is expected to stabilize nucleocapsids, like its HSV-1 homolog.^{560,645} An important enzyme,

the viral protein kinase (VPK, the UL97 gene product),⁴⁹⁴ is incorporated into virions as a tegument constituent and may impact early stages of infection,³⁶⁶ even though its major role is later in facilitating a number of steps during maturation.⁴⁹⁴

Many protein-protein contacts are involved in the organization of the tegument layer. A number of approaches have been employed to recapitulate these interactions, most recently focused on building a systems-level framework of binary relationships between structural proteins.^{474,662} Interactions between pp150 tegument protein and MCP, pUL47/pUL48, and MCP as well as pUL48 and pp28 may help direct envelopment in the AC.⁸⁰ It is likely that many additional contacts serve to establish and maintain the structure of the tegument and provide continuity between the nucleocapsid and the envelope.

The remaining tegument proteins account for a small percentage of virion or dense body proteins,⁶⁸¹ but contribute to entry and maturation (Table 62.1 and Fig. 62.2). One class is involved in replication steps, including disassembly of virions and release of the viral genome into the nucleus, transcriptional regulation, or virion assembly. Other tegument proteins modulate or modify the host cell response to infection, inactivating host cell transcriptional repression mechanisms, blocking intrinsic cell defenses, altering the host cell cycle, and optimizing the intracellular environment for virus replication. US22 family members (UL23, UL24, UL25, UL26, UL29-28, UL36, UL43, IRS1, US22, US23, US24, US26, and TRS1 gene products) modulate host cell signaling and cell death pathways.

Envelope

Virions, dense bodies and other noninfectious virus particles are enclosed in a lipid bilayer envelope derived from cytoplasmic ERGIC or endosomal membranes^{80,653} as depicted in Figure 62.2. Remarkably, as many as 23 different viral glycoproteins have been associated with purified virion and dense body preparations.⁶⁸¹ Some of these contribute to attachment and entry, but most are more likely involved in modulation of the host cell response to infection. In contrast to the alpha- and gamma herpesviruses where a subfamily-specific envelope glycoprotein such as gD (herpes simplex virus type 1 [HSV-1]) and gp350 (Epstein-Barr virus [EBV]) dictates attachment and entry, HCMV relies on homologs of the three major conserved glycoprotein complexes (gC1, gCII, and gCIII, comprised of gB, gM:gN, and gH:gL, respectively). gB and gH:gL are key to attachment and entry, whereas gM:gN is involved in maturation (Table 62.1, Figs. 62.2 and 62.3). These glycoproteins accumulate on internal infected cell membranes as well as on the plasma membrane during infection, and they are the principal targets of antibodies that neutralize virus.⁸⁰

UL55-coded HCMV gB forms a trimer (gC1) on the envelope to mediate membrane fusion in attachment and entry. This is a major target of neutralizing antibody and, like other viral fusion proteins, undergoes a conformational change to fuse the virion envelope and target cell membranes during entry. Based largely on structural comparisons to truncated gB from HSV-1 or EBV,¹³² which are closely related sequence homologs, HCMV gB is a class III fusion protein related to rhabdovirus G and baculovirus gp64. gB mediates binding to heparan sulfate proteoglycan, an initial step in attachment, as well as either pH-independent entry directly at the plasma membrane, as occurs in fibroblasts, or pH-independent entry via the endocytic route, as occurs in endothelial and epithelial

cells.²⁶² gB is not involved in maturation or release of progeny virions, but is important for both cell-to-cell spread and cell–cell fusion leading to syncytia, both of which involve membrane fusion. Cellular receptor(s) for gB are still being investigated. Candidates include cell surface integrins $\alpha 2\beta 1$, $\alpha 6\beta 1$, and $\alpha V\beta 3$ on all cells,²⁶² and particularly $\beta 1$ integrin via a disintegrin-like domain,¹⁸⁶ epidermal growth factor receptor (EGFR) on monocytes,¹⁰⁸ and platelet-derived growth factor receptor α (PDGFR) on endothelial, epithelial, and fibroblast cells.⁶⁰² HCMV receptors (also called entry mediators) may enhance early viral gene expression through signaling pathways, but the role of signaling in entry remains unclear.^{262,434}

Late in replication, as virion maturation proceeds, gB is cleaved by a cellular furin-like protease to generate a 116-kD surface component linked by disulfide bonds to a 55-kD transmembrane component. Unlike the situation with many RNA viruses, proteolytic cleavage is not a requisite for gB function under any conditions that have been studied.²⁶² HCMV neutralizing antibody in convalescent sera recognizes gB as well as other envelope glycoproteins. A soluble form of gB has been shown to elicit protective immunity as an oil-in-water (MF59) adjuvanted subunit vaccine,^{228,456} suggesting that this strategy may lead to a safe vaccine to prevent infection and disease. When administered prophylactically, pooled human gammaglobulin with high gB-specific binding antibody titer has been reported to benefit SOT recipients⁵⁹⁵ and congenitally infected infants.^{359,431} Antibodies that recognize different antigenic domains can inhibit viral attachment or prevent fusion,⁴⁸⁸ reinforcing both aspects of gB function during entry.²⁶²

A second envelope glycoprotein complex (gcII) includes UL100-coded gM and UL73-coded gN. gM may be the most abundant envelope glycoprotein.⁶⁸¹ gM:gN is clearly important during maturation^{307,308} and has not been implicated in entry. gM is an eight-membrane spanning protein that binds heparan sulfate. Experimentally, only a small portion of gM is required for complex formation with gN.³⁵⁷ gN is one of the most highly variable gene products and has been used to track viral strains in disease settings. One particular variant (gN4) has been associated with an increased congenital disease risk.⁴⁷⁹

The third envelope glycoprotein complex is composed of gH (UL75 gene product) and gL (UL115 gene product) that may be modified with additional proteins to control infection in different cell types. The main function of gH:gL is to influence attachment and gB-mediated fusion. HCMV gH:gL and gB together mediate cell fusion more efficiently than gB alone,²⁶² similar to the situation in other herpesviruses.¹³² Therefore, most evidence indicates gH, in particular, controls postattachment enhancement of fusion.²⁶² Detailed crystallographic structural studies completed on HSV-1 and EBV gH:gL¹³² have not provided insight into the gH:gL control of gB activity. gH is a transmembrane protein that requires gL as a chaperone to properly mature.⁸⁰ gH alone, as a component of gH:gL or in other higher order complexes, behaves in ways that suggest it controls the interaction with a cellular receptor,⁶⁷⁹ and although integrin $\alpha v\beta 3$ may be engaged,⁷⁰³ this area remains elusive.

As first shown with EBV, subpopulations of envelope gH:gL associate with additional proteins that act as tropism determinants and dictate entry efficiency for particular cell types. A majority of gH:gL exists as the unmodified heterodimer glycoprotein complex. One additional HCMV component, the UL74-encoded gO, may either be a chaperone^{540,710} or a structural component,⁶⁷⁹

and apparently facilitates entry.^{262,569} In addition to the trimeric gH:gL:gO complex, a pentameric gH:gL complex containing UL128, UL130, and UL131A gene products⁵⁴¹ enhances infection in epithelial and endothelial cells^{539,699} as well as virus interactions with neutrophils, dendritic cells, and many other cell types.⁵²³ This complex may recognize novel receptors to initiate an endocytic entry pathway or facilitate fusion at a postattachment step that follows endocytosis.^{523,539} Viruses lacking components of the pentameric gH:gL:pUL128:pUL130:pUL131A complex enter and replicate without compromise in fibroblasts. Attachment and endocytosis into endothelial and epithelial cells is also independent of the pentameric complex, but the final step of entry into the cytosol is inefficient in its absence.^{539,541} Evidence is accumulating around the pentameric complex that virus particles produced in one cell type differ in biological characteristics from particles produced in another cell type.⁵⁶⁹ For reasons that remain largely unexplained, mutations in UL128, UL130, or UL131A accumulate rapidly as HCMV is propagated in fibroblasts, where entry occurs directly at the cell surface, have given the impression that the pentameric complex expression is deleterious to replication in this cell type.^{262,539,569}

Many of the HCMV envelope glycoproteins that are not directly involved in entry or egress have immunomodulatory potential. The virion contains glycoproteins that bind to IgG encoded by RL11 and UL119-118⁶⁰⁹ as well as secreted glycoproteins, such as the UL22A gene product, the RANTES (Regulated and Normal T Cell Expressed and Secreted) chemokine decoy receptor (Table 62.1) that impact the host response to infection. G protein-coupled receptor (GPCR) homologs encoded by UL33, UL78, US27, and, particularly, US28, have attracted the most attention as immunomodulators. US28 encodes a constitutively strong and ligand-inducible CC/CX3C chemokine receptor,^{202,298,426} long suggesting a role in infection or behavior of virus-infected cells as well as pathogenesis. US28 has been associated with signaling via phosphorylation-, beta-arrestin-, G $\alpha 12$ - and RhoA-dependent activity, and induction of apoptosis and cell migration.^{575,686,690} US27 does not signal but influences viral spread,⁴³⁶ and virion-associated UL33 and UL78 gene products have biological roles that remain unclear.^{575,686,690} Receptor heterodimerization may contribute to the activities of viral GPCRs.⁶⁷⁰

VIRAL GENOME

The genomes of HCMV and closely related chimpanzee CMV align closely, retaining a class E genome arrangement with unique long (U_L) region and unique short (U_S) regions flanked by terminal and internal repeats in an arrangement first described for HSV-1 ($ab-U_L-b'a'c'-U_S-ca$) (see Chapter 59, Herpesviridae) and shown in Figure 62.1. This arrangement of terminal and internal inverted a sequences, which contain the genome cleavage/packaging signals, promotes genome isomerization during replication. Such genome inversion generates four equimolar and independently infectious isomers with regard to the orientation of the short (S) and long (L) genome components. This process is dispensable for replication⁵⁵⁵ and the artificial creation of an inverted copy of the terminal repeat in a viral genome that naturally lacks such repeats, triggers isomerization.³⁸⁶ The c' and c repeats (also called IRS and TRS) flanking the S genome component have a partially duplicated

IE gene set (IRS1 and TRS1) that are conserved in HCMV strains. In contrast, the large *b* and *b'* repeats (also called TRL and IRL) flanking the L genome component originally characterized in the AD169 strain, are apparently the result of extensive cell culture propagation.¹⁴⁹ The RhCMV genome^{239,531} has direct terminal repeats but lacks internal repeats or genome isomerization. Directly repeated *a* sequences of variable length and copy number are found at genome termini and include two herpesvirus-conserved *cis*-acting cleavage/packaging signals, *pac1* and *pac2*. These elements are recognized by the encapsidation machinery to initiate genome packaging and feed the DNA into a capsid as well as to signal cleavage once a genome-length is reached. The cleavage event produces ends with single overhanging 3'-nucleotides, with the location determined by the location of *pac1* and *pac2* motifs.

The viral genome contains an origin of DNA synthesis (*oriLyt*), a second *cis*-acting function, located between the divergent UL57 and UL69 genes in the middle of the U_L region. This position is conserved in all characterized beta herpesviruses. *oriLyt* is required to support viral DNA replication. The *oriLyt* in cytomegaloviruses is large (~1,500 bp) and structurally complex, as assayed in a transient replication assay or within the context of the viral genome.^{21,443} In HCMV, it includes a pyrimidine-rich sequence, reiterated elements, direct and inverted repeat sequences, transcription factor-binding sites, and RNA–DNA hybrids.^{21,443,495}

The HCMV genome has two transcription enhancers controlling IE promoters, a third type of *cis*-acting element, as well as numerous⁶²⁹ transcriptional promoters that become active at different times during infection through a regulatory cascade that controls the behavior of host cell RNA polymerase (RNA pol) II machinery. The best studied is the major IE promoter (MIEP) enhancer, a large genomic region that activates transcription of IE1 (p72) and IE2 (p86). A second complex promoter–enhancer controls US3 IE gene expression. When isolated from HCMV and linked to heterologous genes, the MIEP-enhancer directs efficient transcription in a wide-range of mammalian expression vectors and cell lines. In the context of the viral genome, expression is influenced by cell type and, importantly, is repressed in undifferentiated cells and at late times during productive replication.^{628,629} Therefore, the MIEP enhancer plays a pivotal role in activating viral gene expression immediately following entry into permissive cells, in repressing viral gene expression during latency and in activation of viral gene expression during reactivation.^{510,512,515,628} The enhancer may also function as a latent origin of DNA replication to maintain the viral genome in dividing hematopoietic progenitor cells.⁴⁰³ The MIEP enhancer of HCMV, as well as the analogous enhancer found in other cytomegalovirus genomes, is composed of a dense assembly of transcription factor binding sites that extend over several hundred base pairs of DNA.^{628,629} A *cis*-acting repression signal (*crs*) located between the MIEP TATA box and transcription initiation site interacts with IE2 gene products and shuts down MIEP expression as productive infection proceeds. The different *cis*-acting elements act on host RNA pol II transcription initiation^{628,629} to control the cascade of both protein-coding and noncoding gene products that are made during replication.

Genome Organization and Expression

The conventional depiction of the organization of the HCMV genome (Fig. 62.3), as established in initial published work,¹¹²

depicts one of the four natural isomers with the L component to the left and S component in a multiline layout. Additional considerations and modifications have emerged from genome comparisons,¹⁴⁵ including the current arrangement of protein coding genes RL1-13-UL1-150-IRS1-US1-US34-TRS1 (Table 62.1). The numbering of genes has resulted in the UL148 to UL133 segment being inverted due to the unusual organization of the Toledo strain genome where this region was first characterized.¹⁰⁶ The current consensus genome map omits some potential ORFs and emphasizes a uniform nomenclature.³⁹⁹ A few genes have been added as a result of strain comparisons and empirical mapping, resulting in the current estimate of a minimum of 167 protein-coding genes, plus genes for four large noncoding RNAs, two *oriLyt* RNAs, and at least 23 miRNAs (Table 62.2). The genome includes *cis*-acting signals for replicative DNA synthesis (*oriLyt*), cleavage/packaging (*pac1* and *pac2* within terminal *a* sequences) and the RNA transcription, including the MIEP-enhancer within the U_L (located between UL124 and UL128) and the US3 promoter-enhancer within the U_S region (located between US3 and US6). As in all herpesviruses, genes encoding different HCMV temporal classes of protein-coding and noncoding RNAs are interspersed across the viral genome. For example, the first set of genes to be expressed during infection, IE genes, include the IE1-IE2 locus and the UL36-UL37 locus within U_L, US3 within U_S and IRS1/TRS1 within the S component inverted repeats (Table 62.1). These features are conserved in chimpanzee CMV but diverge in other primate and nonprimate cytomegaloviruses.^{41,369,490,531}

During passage in fibroblasts,^{141,619} both HCMV (AD169, Towne) and RhCMV (68.1) strains accumulate point mutations, deletions, and duplications such that common laboratory strains lack as many as 20 genes while retaining a consistent genome size through sequence duplication.¹⁰⁶ A common duplication affects a large segment of the RL region,¹⁰⁶ which is naturally part of U_L (Figs. 62.1 and 62.3). It should be noted that HCMV strains do not spontaneously lose any of the many genes that are dispensable for replication. Despite spontaneous deletions, HCMV maintains a consistent, 236 kbp genome size.^{145,166,399,727}

HCMV genome annotation remains provisional. Protein-coding regions shorter than about 80 codons or regions overlapping larger ORFs have typically not been included unless verified as biologically functional.^{145,399} The refinement of HCMV annotation has included many methods, including comparisons of strains to unpropagated HCMV, chimpanzee CMV, alternative algorithms, and relating protein composition to coding capacity. Liberal estimates of coding capacity,⁴¹⁸ improved annotation methods,⁸² transcriptome analysis,²⁰⁴ and ribosomal profiling⁷⁴¹ all contribute to the current estimate. The functional analysis of HCMV genes has generally followed one of two strategies. Many viral genes have yielded biological activity when studied in isolation or when mutated in the virus. Many have revealed their function through a specific phenotype in viral replication, pathogenesis, immune modulation, or latency. Alternatively, directed or random mutagenesis of viral genomes has yielded phenotypes that define biological function during replication or pathogenesis. The virus strain, host cell type, precision of the mutagenesis, and approaches to evaluation may all impact the physiological relevance of the data that is generated by either approach. A wider

variety of viral gene products have been studied in isolation than have been studied in the context of viral infection, which leaves the physiological function of many gene products in need of further study. The genome complexity of HCMV, together with the range of settings where this virus interfaces with host cell and host defense pathways for replication, persistence, pathogenesis, and latency provides opportunity for additional insights to emerge.

Although different strains of HCMV exhibit >95% DNA sequence homology, certain regions exhibit a high interstrain variability. UL73, UL74, UL144, and UL146 glycoprotein genes, in addition to the terminal repeat α sequence, are the most polymorphic (Table 62.1), variability that has been very useful in tracking viral genome transmission in clinical settings. These polymorphic genes have been used in attempts to correlate particular genotypes with disease as well as for assessing geographic distribution of strains and to establish the level of recombination between strains in reinfected individuals. Recent deep sequence evaluation of viral genomes in clinical samples has revealed a truly immense level of variation that occurs within infected individuals¹³⁹ and has suggested that HCMV undergoes error-prone replication with sequence variation levels as high as some RNA viruses.⁵²⁰

HCMV encodes 23 miRNAs (Table 62.2) during productive viral replication.^{168,221,473,623} In contrast to alpha herpesviruses and gamma herpesviruses, where miRNAs are clustered, HCMV miRNA genes are dispersed across the genome. All but miR-UL70-1-5p, which has not been tested, associate with Argonaute protein silencing complexes⁶²³ and initiate a diversity of biological consequences.^{156,674} Most mature miRNAs that have been assayed²²¹ show DE kinetics, except miR-UL70-1, which shows an IE pattern. Many of the miRNAs are in regions of the genome known to be dispensable for replication in fibroblasts (e.g., miRNAs mapping to US4, US5, and US22), such that no single virus-encoded miRNA is crucial for replication. Several play accessory roles modulating gene expression that influences cell behavior or host response, and may be important in pathogenesis. The sequences of miRNAs are not conserved between herpesvirus subfamilies or even between human beta herpesviruses HCMV and HHV-6B.⁶⁷³ Although conservation between HCMV and chimpanzee CMV²²¹ limited (miR-US5-2) conservation with RhCMV have been noted,²³⁵ MCMV carries a completely unique set of miRNAs.^{88,160} More work will be needed to determine whether the lack of sequence conservation reflects a type of evolutionary divergence that immunomodulatory proteins are already known to exhibit. HCMV encoded miRNAs have not yet been demonstrated during the latent phase of infection, although cellular miRNA has been implicated in a CD34+ cell model of latency.⁴⁸⁵

REPLICATION

HCMV pathogenesis involves productive replication in a variety of cell types,^{81,523} including epithelial, endothelial, neuronal, myeloid, and fibroblast cells. Most studies aimed at understanding viral replication properties have been carried out in fibroblasts, a stromal cell present in all tissues of the host. The ease of studying HCMV replication in these cells, together with significantly greater yields of virus and gene products,⁶⁶⁸ has made it possible to establish the main themes

of viral gene expression and regulation, DNA synthesis and maturation (Fig. 62.2). Viral tropism differences for various cell types were initially recognized through studies employing clinical strains propagated on either cultured endothelial or myeloid cells, including vascular endothelial cells, macrophages, and dendritic cells.⁵⁸³ Viral strains propagated in this manner retained tropism characteristics that are lost during propagation on fibroblasts, but still accumulate mutations.¹⁴¹ Cell lines such as ARPE-19 epithelial cells proved useful in studies of viral tropism determinants. Clinical isolates must undergo adaptation to replicate efficiently in fibroblasts, overcoming poorly understood negative impacts of RL13 and UL128-UL131A¹⁴¹ that drive genome mutations in fibroblasts.⁶¹⁹ Evidence clearly shows that loss of any one of three components (pUL128, pUL130, and pUL131A) of the gH:gL pentameric complex compromises replication efficiency on epithelial and endothelial cells.^{523,539,541,698}

Following entry, three kinetic classes of genes, IE (or α), delayed early (DE or β) and late (L or γ), are expressed sequentially in a coordinately regulated manner over the course of a 48 to 72 hour productive replication cycle. Expression of major IE gene transcription is controlled by upstream enhancers on the viral genome as well as a tegument protein (pp71) that acts as the virion transactivator to increase expression. IE gene expression depends upon preformed host and viral machinery and is independent of *de novo* viral or host expression. Host cell RNA pol II and related transcription machinery controls transcription of the viral genome throughout infection, although transcription is regulated via virus-encoded transactivators. Translation depends entirely on host cell ribosomes. Expression of DE genes is required for viral DNA synthesis and requires expression of functional IE gene products. The DE class of β genes may be further divided into early-late subclasses, β_1 and β_2 , which differ in the pattern of expression.³⁹⁹ Expression of L genes is dependent on expression of DE genes and includes gene products that form virions and control maturation. Two distinct categories of L genes are recognized as leaky late, or γ_1 and true late, or γ_2 , based on the pattern of expression and dependence on viral DNA synthesis.³⁹⁹ Similar to other herpesviruses, the expression of most HCMV L genes is leaky, and occurs independent of viral DNA synthesis though dependent on DE gene expression. Typically, viral DNA synthesis inhibitors such as foscarnet (phosphonoacetic acid) have been used to block viral DNA synthesis to assist in dissecting DE and L patterns of gene expression. The leakiness of late gene expression and the recognition of kinetic subclasses spawned the alternate terminology— α , β , and γ —first used to describe HSV-1 patterns. Although the replication cycle of HCMV is slow, requiring 48 to 72 hours to reach final stages of maturation and release of progeny, the expression of IE gene products starts within minutes of infection. The switch from early phase to late phase is prolonged, from 24 to 36 hours postinfection (hpi) and may be even longer dependent on cell type. Initiation of IE gene expression is sensitive to cell cycle status, linked to regulation of p53,⁷³⁹ such that cells in S, G2, or M phases do not produce IE proteins until cells return to G1. Maximum levels of virus progeny are released from fibroblasts starting around 5 days postinfection and continue for several days before cells die, succumbing to a serine protease-dependent programmed death pathway the timing of which is controlled by the viral mitochondrial inhibitor of apoptosis (vMIA).³⁷⁷

Attachment and Entry

Entry occurs in distinct steps³⁹⁹: (a) binding to specific cell surface receptors, (b) viral envelope fusion with cellular membranes to release nucleocapsids into the cytoplasm, either directly at the plasma membrane (as occurs in fibroblasts) or after endocytosis into cells (as occurs in endothelial and epithelial cells), (c) nucleocapsid translocation toward the nucleus on cytoskeletal filaments, (d) nucleocapsid interaction with nuclear pores, and (e) release of the viral genome into the nucleus (see Fig. 62.2). At the same time, independent of nucleocapsid translocation to the nucleus, tegument proteins are released into the cytosol and traffic to sites where they function in diverse ways, modulating the initial host response to infection and orchestrating the transcription of IE genes. This process has common characteristics among all herpesviruses, so understanding of how these steps are controlled comes from direct study of HCMV as well as from surrogates such as MCMV, guinea pig CMV, and simian CMV, as well as comparisons to other herpesviruses. Initial contact with cells is via cell surface heparan sulfate, a feature common to many herpesviruses. Investigations have shown that envelope glycoproteins gB and gM bind heparan sulfate, and may overlap to make initial contact with cells.²⁶² HCMV attachment does not require dedicated subgroup-specific receptor-recognizing envelope glycoprotein, such as gD (HSV-1/HSV-2) or gp350 (EBV).^{132,285} Instead, HCMV completes attachment as well as fusion steps with herpesvirus-conserved gB and gH:gL. Initial binding of virions to cells leads to a cascade where gB trimers and gH:gL heterodimers orchestrate events through sequential cellular receptors that ultimately results in fusion between the viral envelope and cell membrane,²⁶² and release of the nucleocapsid and tegument proteins into the cytoplasm. This entry step is disrupted when cholesterol is reduced.²⁷⁵ In addition to the major envelope glycoproteins controlling entry into any cell type, a trimeric complex consisting of gH:gL:gO and a pentameric complex comprised of gH:gL:pUL128:pUL130:pUL131A facilitate entry in certain settings.^{523,582} The pentameric complex facilitates attachment and entry into epithelial and endothelial cell types,^{523,541,698} suggesting that this complex may play an important role in HCMV pathogenesis. Additional entry options have come to light, such as the requirement for pUS16 to mediate efficient viral infection of endothelial and epithelial cells when the pentameric gH:gL complex is absent.⁸³

Considerable attention has been focused on gB because of its common role in attachment and fusion of all herpesviruses, mediating delivery nucleocapsids into the cytosol. Several receptor and entry mediator candidates have been shown to interact with gB. Some of these have turned out to be dispensable for infection of susceptible cells.¹³¹ In this regard, β_2 microglobulin, annexin II, and aminopeptidase N (CD13) are unlikely receptors for viral entry. More recent identification of cell surface integrins $\alpha 2\beta 1$, $\alpha 6\beta 1$, and $\alpha V\beta 3$,²⁶² as well as EGFR on monocytes¹⁰⁸ and PDGFR on endothelial, epithelial, and fibroblast cells,⁶⁰² remain under evaluation. Furthermore, host membrane characteristics conferred by tetherin expression enhance entry.⁶⁸⁷ In addition to mediating the delivery of the nucleocapsid to the cytoplasm, the interaction of HCMV envelope glycoproteins with cell surface proteins may trigger cellular signaling pathways to enhance viral and cellular gene expression to facilitate infection.²⁶² Toll-like receptor 2 (TLR2) is one such candidate on monocytes. Candidate receptors have also been found to

interact with gH, including $\alpha v\beta 3$ integrin.¹³¹ Although there is little question that HCMV enters cells through specific interactions between major envelope glycoproteins and cellular plasma membrane receptors, much remains to be learned about the pathways that are involved.^{131,262,399,523}

Intracellular Trafficking and Uncoating

Once the HCMV nucleocapsid is deposited into the cytoplasm, cytoplasmic microtubules are predicted to facilitate translocation to the nucleus where viral DNA is released.³⁹⁹ In HCMV, the large tegument protein (LTP; UL48), as well as a binding protein (LTPbp; UL47) play essential roles in replication,^{167,727} potentially analogous to the HSV-1 UL36 gene product, controlling uncoating and release of viral DNA from nucleocapsids. Both HCMV UL47 and UL48 are likely to be important for replication,^{80,400} but so far only viral mutants in a dispensable deubiquitinating function of UL48 have been studied.²⁹³ Greater focus on uncoating and nucleocapsid translocation to nuclear pores is needed.

IE Gene Regulation and Function

Once the HCMV genome is delivered to the nucleus, IE gene expression ensues. RNA pol II transcription machinery transcribes IE as well as all other protein-coding and noncoding RNAs made from the HCMV genome. Regulation of viral gene expression occurs via two broad strategies: (1) viral as well as cellular factors that directly influence the transcription machinery by binding to promoter/enhancer elements directly (transcription factors) or through interactions with other proteins (adaptors) and (2) viral factors that alter chromatin remodeling by regulating the opposing activities of histone acetyl transferases (HATs) acting together with demethylases and histone deacetylases (HDACs) and methylases. HDAC-dependent repression of viral IE gene expression, in particular, is a cell-intrinsic host defense mechanism that must be defused before productive replication can ensue. Epigenetic regulation is important in permissive cells, even though the viral genome does not take on a recognizable chromatin structure, and also during latency, where viral genomes take on an organized chromatin arrangement and viral HDAC inhibitors can drive reactivation.^{510,512,579}

The regulation and activities of IE gene products have been a focus of considerable review.^{399,510,512,579,628,629,631,707} Five loci distributed across the viral genome give rise to IE gene transcription (Table 62.1), UL36 and UL37, IE1 and IE2 (UL122 and UL123), TRS1, IRS1, and US3. IE1/IE2 and US3 gene expression is under control of independent transcriptional enhancers. The major IE (MIE or IE1/IE2) gene is transcribed from the MIE promoter (MIEP) into alternatively spliced and polyadenylated mRNAs encoding two predominant nuclear phosphoproteins, IE1-p72 and IE2-p86, along with minor IE proteins. Although IE2-p86 is recognized as the most important viral transactivator and key to viral gene expression during productive replication, IE1-p72 and IE2-p86 together defuse epigenetic repression, activate DE and L classes of viral genes during productive replication, autoregulate IE gene expression, and establish nuclear sites where lytic viral DNA synthesis proceeds. In addition, these major IE proteins contribute in crucial ways to the switch between latency and reactivation.

MIEP expression is dependent on a transcriptional enhancer (also called the HCMV enhancer) that is subject to positive- and negative-acting viral and cellular chromatin

remodeling pathways controlled by HATs and HDACs acting together with methyltransferases and demethylases.^{510,512,579} This locus is the only region of any cytomegalovirus genome known to exhibit CpG suppression, consistent with a need for the region to remain unmethylated during latency and reactivation.⁶²⁹ No matter the cell type, epigenetic repression of the MIEP must be relieved by the concerted and sequential activity of tegument proteins such as pp71 and ppUL69 and the major IE proteins IE1-p72 and IE2-p86, acting with other viral proteins and host transcription machinery to sustain viral gene expression over the very long HCMV replication cycle.^{323,374,654} The failure of HCMV to replicate in cells that have entered S phase is due to the inability of these viral functions to overcome epigenetic repression⁷⁴⁰ and is associated with the failure to encode IE proteins.⁵⁵⁰

Individual MIE proteins counteract cell-intrinsic resistance mechanisms triggered by viral infection.^{427,512} MIE proteins IE2-p86 and IE1-p72 induce cell cycle arrest with prodeath or pro-survival impact depending on the setting.^{377,427,631} MIE protein IE1-p72 binds chromatin,^{516,576} orchestrates STAT (Signal Transducer and Activator of Transcription) signaling,⁴²⁷ disrupts nuclear domain 10 (ND10; also called promyelocytic leukemia protein [PML] bodies or PML oncogenic domains [PODs]),^{323,374,654} in addition to binding HDACs⁵⁷⁶ and Daxx^{511,512} and contributing to chromatin remodeling and direct regulation of gene expression.

Three additional IE regions (UL36/UL37, TRS1, and IRS1) encode functions that modulate other aspects of the cell-intrinsic response to viral infection in addition to their direct impact on gene expression, and one IE gene (US3) is involved in posttranslational down modulation of MHC class I gene levels on the host cell to evade cytotoxic T-cell surveillance. UL36, UL37 × 1, UL37 × 3, TRS1, and IRS1 are each individually dispensable for viral replication in fibroblasts; each carries out modulatory activities that contribute to viral pathogenesis. The US3 protein is the earliest viral protein disrupting MHC class I antigen presentation to make infected cells less attractive targets for cytotoxic T-cell immune surveillance⁴⁸⁰ and will be discussed together with other US2 and US6 family members.

UL37 × 1 encodes the very potent mitochondrial cell death suppressor, vMIA. This small protein localizes to the outer mitochondrial membrane and sequesters Bax and Bak, but does not prevent oligomerization of these Bcl2 family members or mitochondrial fission that results from this association.^{286,435} Through interactions with Bax, Bak, Bcl_L, and GADD45 family members, vMIA prevents cytochrome *c* release, the key step in the activation of executioner caspases driving apoptosis.³⁷⁷ vMIA associates with endoplasmic reticulum (ER)-derived mitochondrial-associated membranes,^{75,711,713} increases ER release of calcium stores, and enhances cell rounding⁵⁷⁴ and, as a consequence, vMIA has been associated with HCMV cytopathic effects mediated through viperin.⁵⁷³ Although vMIA is a very potent inhibitor of apoptosis,³⁷⁷ its role in HCMV infection is to prevent a novel mitochondrial HtrA2 serine protease-dependent death pathway that terminates the viral replication cycle in fibroblasts.³⁸⁰ Because of its role in titrating out mitochondrial proteins that antagonize infection, vMIA may appear essential for replication (e.g., AD169) or dispensable for replication (e.g., Towne). Small mitochondrial Bax and Bak inhibitors with sequence characteristics of UL37 × 1 are evolutionarily conserved in beta herpesviruses.³⁷⁷ MCMV

encodes two mitochondrial-localized cell death suppressors with related function, m38.5/vMIA and m41.1/vIBO, that independently target Bax^{26,435} and Bak,⁹¹ respectively.

UL36 is a US22 family member that encodes the viral inhibitor of caspase 8 activation (vICA).³⁷⁷ vICA suppression of extrinsic apoptosis is crucial for viral infection of macrophages,^{123,379} but apparently dispensable for replication in other cell types. HCMV UL36, as well as the RhCMV homolog are mutated in commonly used strains.⁵⁸⁵ UL36-encoded vICA binds procaspase 8 and prevents cleavage/activation, behaving in a manner that is mechanistically similar to the long form of cellular FLICE (another name for caspase 8) inhibitory protein (cFLIP_L). vICA is highly conserved, with a homolog encoded by all beta herpesviruses. The contribution of vICA-associated caspase 8 suppression during infection and pathogenesis comes from studies using MCMV mutant viruses in mice.¹²³ Viruses that lack vICA replicate fine in fibroblasts but are attenuated due to susceptibility to extrinsic apoptosis in macrophages.^{123,377,405} The evolutionary acquisition of multiple cell death suppressors in HCMV and MCMV has facilitated identification of programmed necrosis as a bona fide host defense pathway that evolved in mammals to defend against viruses.⁴⁰⁵ Necrotic death is triggered by vICA suppression of caspase 8, causing release of receptor interacting protein (RIP) kinase 3 to form a complex with DNA-dependent activator of interferon signaling (DAI)⁶⁷⁷ and is inhibited by MCMV M45-encoded viral inhibitor of RIP activation (vIRA).⁶⁷⁸ An HCMV RIP inhibitor has not been identified.

IRS1 and TRS1 are highly homologous US22 family members that inhibit interferon-inducible protein kinase R (PKR).³⁷¹ Either must be retained in order for viral replication to proceed.³⁷⁰ Independent of PKR, TRS1 inhibits macroautophagy,¹¹¹ and TRS1, more than IRS1, may influence DE gene expression, DNA synthesis,^{278,634} and capsid assembly,³⁷¹ all of which may ultimately be related to inhibition of PKR.³⁷⁰

Regulation of MIEP Enhancer

The MIEP-enhancer is a common tool for eukaryotic expression vectors in experiments and commercial production of biologics because it is constitutively active and strong.⁵⁶¹ In the context of the viral genome, the MIEP-enhancer is epigenetically silenced and requires the activity of input viral tegument proteins pp71 and ppUL69 as well as IE and DE proteins that are made during infection to remain active.^{579,628,629} Regulation focused on cellular chromatin remodeling machinery bears on models of viral latency and reactivation where MIEP expression is key to this switch.⁵¹² Mutations within the MIEP enhancer result in viruses that exhibit MOI-dependent growth properties and that are compromised in models of latency and reactivation.^{512,628,629} Once released from nucleocapsids following entry, HCMV genomes delivered to the nucleus associate with ND10, in a manner that has been observed in many herpesviruses and other DNA viruses.³⁷⁴ Initiation of IE gene transcription, modulation of cell intrinsic signaling, and inhibition of the DNA damage response all take place in association with ND10,¹⁷⁹ which becomes disrupted by IE1-p72, even though this disruption is dispensable for viral replication.⁵⁷⁶ Relief from HDAC-mediated repression is initially carried out predominantly by the tegument protein pp71, encoded by UL82, is the principal virion transactivator (VTA) of HCMV. VTA relieves HDAC repression^{511,512,628} by localizing to ND10, degrading Daxx to

prevent Daxx/ATR-X-mediated repression of the MIEP, which is mediated via HDACs.^{258,352,430,492} These properties of pp71 make it useful in experimental settings to increase production of infectious virus following transfection of viral DNA or bacmids. pp71 associates with tegument protein ppUL35,⁵⁵⁹ an HCMV DNA damage response modifier.⁵⁴⁵ Upon entry, the pp71:ppUL35 tegument complex more efficiently stimulates MIEP expression than pp71 alone, whether surveyed in reporter assays or in the context of virus infection.⁵⁵⁹ Viral mutants lacking UL82 or UL35 exhibit MOI-dependent replication similar to that observed with IE1-p72, MIEP enhancer, and *crs* mutant viruses.^{628,629} Following the initiation of IE gene expression, HDAC suppression is sustained by IE1-p72.

Other tegument proteins contribute to optimal MIEP expression. Virion ppUL69 enhances the initial stages of viral infection, although it has its major impact later in infection. ppUL26 is a transcriptional activator of the MIEP that probably regulates phosphorylation levels of other tegument proteins,⁴¹³ and pp65 activates the MIEP possibly by recruiting the cellular IFI16 protein to the control region.¹³⁷ ppUL29/28, encoded from a spliced mRNA, stimulates MIE gene expression by modifying the HDAC1-containing nucleosome remodeling and deacetylase protein (NuRD) complex, handing off to pUL38 in association with the MTA2 component of NuRD at early times in infection.^{396,656} As infection proceeds, MIE gene products impose additional regulation on the MIEP enhancer, as described in the next section. In addition to the viral proteins, cellular signal transduction pathways induced by virus particles or other factors such as serum growth factors as well as cell type and cell cycle state, impact MIEP expression. This is particularly evident at low MOIs as well as in particular cell types.⁵⁷⁹

Mutation and substitution of enhancer components have reinforced the role of the MIEP enhancer in the initiation of viral gene expression during replication. The MIEP enhancer is composed of an upstream region (−580 to −300 relative to the transcription start site) that is less important in most assays than the proximal region (−300 to −39 relative to the transcription start site).^{628,629} The multitude of transcription factor binding sites contributing to enhancer activity during infection^{628,629} includes multiple cyclic AMP response element binding protein ATF/CREB and NF-κB binding sites. Investigations have shown that many can be disrupted without compromising replication, consistent with a highly redundant role for this complex transcriptional control region. Substitution experiments replacing MIEP enhancers have shown that MCMV carrying a HCMV enhancer replicates normally in mouse fibroblasts, but not in mice. The MCMV enhancer does not work in HCMV, but the simian CMV enhancer confers normal growth levels and plaque efficiency on HCMV.^{628,629} These experiments reinforce the role of the enhancer as a critical *cis*-acting signal for MIE expression as well as some level of evolutionary adaptation to the homologous host species within the context of the viral genome.

IE1 and IE2

The principal products of the MIE gene, IE1-p72 and IE2-p86, result from alternative mRNA splicing that places 85 amino terminal amino acids together with carboxyl terminus derived from UL123 and UL122, respectively. Both of these proteins are primarily involved in regulating viral transcription to initiate productive replication as well as the latency-reactivation axis, although expression from this locus is not sufficient to drive reac-

tivation.^{512,628,629,707} These proteins modulate the host cell response to infection,^{367,654} acting in concert with virion tegument as well as other IE gene products to establish a cellular environment to support replication. IE2-p86 is both a crucial activator of later kinetic classes (DE and L) of viral genes as well as a repressor of MIE expression,⁶³¹ whereas IE1-p72 functions primarily as a coactivator together with IE2-p86.²⁰⁵ IE1-p72 disrupts ND10^{374,629} and sustains an open chromatin configuration initiated by the VTA, and probably acts independent of VTA in reactivation from latency.⁵¹¹ In addition, less abundant IE proteins IE1-p38, IE2-p55, and IE2-p18, have no known function.⁶²⁹ Later during infection, abundant leaky L (p60) and true L (p40) proteins are made from independent promoters embedded within UL122, and these are colinear with the carboxyl terminus of IE2-p86. Although both of these have the ability to repress MIE expression by binding to the *crs*, neither plays a crucial role in replication.^{629,706}

IE2 proteins that share the carboxyl-terminus of IE2-p86 all negatively autoregulate expression from the MIEP by binding to the minor groove of the *crs* between −13 and −1 relative to the transcription start site (CGTTTAGTGAACC^{−1}), thereby blocking transcription by inducing a repressive chromatin state^{509,510} rather than by disrupting transcription by RNA pol II more directly. This was the first IE2-p86 binding site identified in the HCMV genome, but there are many others within the promoters of DE and L genes that enhance transcription. A sequence related to the *crs* in the US3 gene (CGT^G/T-CAGTCCACACG⁺¹) is repressed by ppUL34 rather than IE2-p86.^{55,629} The highly abundant leaky L 60-kD and very abundant L 40-kD (L40) IE2 proteins, once thought to maintain repression throughout infection, are largely accessory. Only IE2-p86 appears crucial for the activation and repression necessary to complete viral replication.⁷⁰⁶

The major function of IE1-p72 and IE2-p86 is to mediate activation of viral genes expressed through the remainder of infection.⁶²⁹ IE1-p72 and IE2-p86 associate with ND10. IE1-p72 disrupts these domains and undermines ND10-dependent activation of interferon (IFN), but does not alter their organizational role in viral gene expression or in initiation of viral DNA synthesis. Although an independent role of IE1-p72 in counteracting IFN activation is established,⁴⁵⁹ infection with IE1-p72-deficient virus at an MOI greater than 1 leaves ND10 intact and replication at levels similar to that of wild-type virus. The theme established by pp71 continues with the MIE genes, and IE1-p72 inactivates HDACs associated with ND10 to facilitate efficient, IE2-p86-dependent DE and L gene expression.^{511,512,631} Although normally disrupted by IE1-p72, the ND10 areas become sites of DNA synthesis independent of IE1-p72 function, starting with ppUL84 associating with IE2-p86, attracting UL112-113 gene products and viral replication complex proteins to initiate viral DNA replication.^{21,278,295,443} The replication defect of IE1-p72-deficient virus at low MOI likely results from failure to inactivate HDACs and allow for adequate activation of DE gene expression rather than either a failure to disrupt ND10, suppress the IFN response, or initiate DNA replication.^{511,512} It should be noted that the UL97 kinase⁶⁶⁷ and other gene products expressed later in infection (UL30, UL35, and US32) alter PML morphology or disrupt ND10.⁵⁴⁶

HCMV IE2-p86, a major nuclear phosphoprotein, is crucial for replication, although exact mechanisms have proven difficult to establish because of technical difficulties with conditional

mutant viruses that have been made. This gene has been subjected to extensive mutagenesis and evaluation by transient assay and many mutants have been built into virus constructs that fail to replicate. Most attention has been focused on the full-length MIE product, IE2-p86, the only UL122 gene product that is absolutely necessary for replication. The additional IE, DE, and L gene products encoded in the UL122 region are completely dispensable.^{90,551–553,631,706,707} The MCMV homolog (called ie3) seems to function analogously to HCMV IE2-p86,^{314,372} although the MCMV homolog of HCMV IE1 (called ie1) and a novel MCMV ie2 gene are dispensable for all aspects of viral infection⁷⁰⁸ and fail to contribute to transcriptional patterns during infection.³¹⁴ HCMV IE2-p86 transactivates promoters through direct interaction with DNA (the MIEP *crs* and many other *crs*-like sites distributed throughout the genome), influencing RNA pol II transcription machinery directly by interacting with p53, cdk9 and cdk7, cycinT1, Bed4, HDAC1 and HDAC2 in a viral transcriptosome^{283,284} as well as via epigenetic regulation, and employing functional domains that are located in both amino-terminal and carboxyl-terminal regions of the protein.^{631,707} In the absence of IE2 mutant viruses to reveal core aspects of IE2-p86 function, transient assays defined IE2-p86 domains that are important for positive or negative regulatory impact, and these have proven useful. The regions contributing to transactivation include two domains located between aa 25 and aa 85 as well as between aa 544 and aa 579, at the extreme carboxyl terminus, as well as dimerization (aa 388 to 542) and helix-loop-helix aa (463 to 513) regions that overlap a core region (aa 450 and 544) important for most associated activities.^{631,707} The 450 to 544 region directs the interaction with a number of cellular transcription factors that have been implicated in regulation by IE2-p86,^{283,284} as well as for interaction with the viral UL84 protein, which counteracts IE2-p86 transactivation function but is crucial for initiation of DNA replication. IE2-p86 also interacts with a broad number cell cycle regulated proteins, sustaining the unique cell cycle block instituted during infection. Transactivation involves an adapter-like protein stabilizing RNA pol II transcription factor D TFIID-associated factors on the promoters, interacting with the carboxyl terminus of TATA element binding protein TBP and TFIIB.^{631,707}

DE Gene Regulation and Function

Following peak expression of MIE regulatory proteins, between 8 and 12 hpi, the second class of early genes, DE, become transcriptionally active independent of the host cell type.⁶⁶⁸ Although some DE gene products are produced in abundance from the start, most of the 65 proteins (Table 62.1) and assorted miRNAs (Table 62.2) accumulate gradually. The DE period of viral replication continues through 18 to 24 hpi when viral DNA synthesis initiates. DE genes are crucial for viral DNA synthesis and include several functions that become important later in infection for maturation and egress. Many DE genes have a substantial impact on replication when disrupted.^{167,727} DE gene products dispensable for replication in fibroblasts may contribute to modulation of the host cell and host animal response to infection. Several HCMV DE genes switch or add transcriptional start sites later in infection, which means that transcript levels represent the combined products of different kinetic classes of gene expression.

The principles of DE gene regulation⁷⁰⁷ are intertwined with subversion of host cell cycle regulated pathways⁵⁵⁰ and

both depend on the key regulatory protein IE2-p86 functioning together with a number of collaborating factors.^{629,631} The promoter regions of three DE genes (UL112-UL113, UL54, and UL4) have been studied in detail. Although transient cotransfection assays first revealed candidate transcriptional control elements in the promoters for these genes, it was only after mutations were introduced into the viral genome and evaluated in the context of infection that concrete information emerged. The activation of these three genes illustrates the subpatterns of early gene expression that is dependent on IE gene expression as well as the differential regulation by host and viral functions as infection proceeds. Expression of the UL112-113 transcripts⁷⁰⁷ that are differentially spliced to yield four unique proteins (pp34, pp43, pp50, pp84), starts by 8 hpi and remains constant through L times (β_1 pattern). Transcription shifts to a different start site at L times but the same mRNA splicing pattern and a single polyadenylation site is used throughout infection. Promoter-proximal ATF/CREB and IE2-p86 binding sites are important for sustained transcription throughout infection, with the ATF/CREB site more important early and the IE2-p86 binding site more important at L times. Expression of UL54,⁷⁰⁷ encoding DNA POL, starts by 8 hpi and increases steadily through L times (β_2 pattern), relying on a single transcription start site but two polyadenylation sites. Unlike L genes discussed in the next section, expression of β_2 genes is not reduced in the presence of viral DNA synthesis inhibitors. Promoter-proximal SP1 and IE2-p86 binding sites are more important early, and an ATF/CREB site is crucial for the increase at L times during infection, although the transcription start site remains unchanged. Finally, UL4,⁷⁰⁷ which encodes a minor virion envelope glycoprotein (gp48), shows a transcription pattern during infection that is similar to UL54 (β_2 pattern), but this gene is predominantly regulated at the translational level by ribosome stalling.^{54,543} Transcriptional activation is dependent on Elk-1 and IE2-p86 binding sites in the promoter plus some consequence of MAPK signaling that acts via the TATA element. Translational stalling is dependent on a carboxyl-terminal Pro within a 22 aa ORF (uORF2) within the transcript upstream UL4, thereby preventing full expression of gp48. Translation stops because uORF2 fails to release peptidyl tRNA dependent on the release factor eRF1,⁵⁴³ and this blocks the large ribosomal subunit exit tunnel and halts the ribosome.⁵⁴ Although elegant studies have deduced that this form of regulation is common across eukaryotes and prokaryotes, the natural context for this exquisite level of regulation as well as a mechanism to relieve inhibition in HCMV remain to be elaborated.

A number of DE gene products regulate gene expression. pUL34 is a specific repressor of US3 expression, acting on a novel *crs*.³²⁸ Four UL112-113 gene products (pp34, pp43, pp50, pp84), function together with IE1-p72, IE2-p86, and TRS/IRS to modulate DE gene expression, UL21A enhances replication at early times,^{184,185} and DE proteins contribute to continued suppression of epigenetic repression by HDACs. UL26 activates the MIEP,^{349,413} pUL38 antagonizes the tuberosclerosis complex to prevent ER stress (407 Qian, 2011 #7341), and pUL29-28 stimulates gene expression by interfering with HDACs, modifying the nucleosome remodeling and deacetylase (NuRD) complex^{396,656} to sustain derepression of the MIE gene throughout infection. In addition, UL97 promotes KAT5/Tip60 HAT phosphorylation to increase expression³³⁰ and UL27 inhibits KAT5/Tip60 HAT and suppresses

expression of cyclin-dependent kinases.⁵¹⁸ Finally several abundant tegument proteins, including pp65, pp71, pp150, and LTP/ppUL48 are transcriptionally active as DE genes, although their activities support virion maturation or steps during infection of subsequent cells.

Cellular gene expression is activated during HCMV infection. Global transcription^{204,246,434,623,668} and, most recently, global proteomic/metabolic analyses,^{412,549} has shown the extensive stimulation of cellular lipid metabolism and energy pathways to favor HCMV replication, contrasting with the extensive shut-off of the host cell by HSV.⁶⁸² Viral replication and maturation follow stimulation and parallel accumulation of viral DNA synthesis functions, giving the impression that the prolonged replication cycle of this virus may require sustained cellular functions and proceeds only as they become available.⁵⁵⁰ HCMV infection stimulates cellular RNA as well as protein synthesis while completely dysregulating the cell cycle⁵⁵⁰ such that infected cells appear to be at G₁/S, G₂, or even M. Some of this comes as a result of dysregulation of cellular cyclin-dependent kinases²⁴⁶ and mislocalization of proteins normally associated with checkpoint control to sites of viral maturation in the cytoplasm.²⁰³ In fibroblasts, cellular DNA synthesis is usually held in check as a pseudo-G1 block,²⁴⁶ with contributions from tegument proteins, pp71 and ppUL69, as well as IE2-p86 in maintaining this cellular environment.⁵⁵⁰ Systems level analyses have repeatedly confirmed more focused earlier assessments showing that glucose metabolism,^{731,732} mitochondrial energy production,^{377,711} and cell cycle-regulated expression⁵⁵⁰ are all broadly activated, whereas cytoskeletal, extracellular matrix, adhesion functions, and cellular DNA synthesis⁵⁵⁰ are broadly down modulated.

One abundant noncoding RNA, the $\beta 2.7$ /RNA2.7, accumulates to represent more than 60% of total viral polyadenylated transcripts at L times of infection.^{204,668} This most abundant DE gene product is dispensable for replication³⁸⁴ but associates with mitochondrial complex I (nicotinamide adenine dinucleotide-ubiquinone oxidoreductase) to stabilize ATP production and prevents apoptotic cell death when respiration is blocked by rotenone treatment⁵¹³ as well as necrotic death from ischemia/reperfusion injury.⁷³⁷ Although naturally a noncoding RNA, the $\beta 2.7$ /RNA2.7 promoter allows for high-level expression of heterologous genes, regulated with DE kinetics, within the HCMV genome.⁶⁰⁵

DNA Synthesis and Nucleotide Metabolism

Lytic HCMV DNA synthesis occurs within the nucleus of infected fibroblasts, starting as early as 14 to 16 hpi, increasing by 24 hpi, and reaching greater than 10,000 viral genome copies per cell⁶⁶⁸ at the time progeny virions start to form.^{21,443} In fibroblasts, viral DNA labeled for 1 h at either 19 or 23 hpi quantitatively chases into maturing virions and leaves the cell via the cytoplasm over the next 24 to 48 hours.⁴⁶⁷ In epithelial and astrocytoma cells, viral replication is more subdued and maximal viral DNA levels do not exceed 1,000 viral genomes per cell.⁶⁶⁸ DNA synthesis initiates from the complex oriLyt site between the UL57 and UL69 genes (Fig. 62.3), although the mechanism is still unclear. The HCMV, MCMV, or GPCMV oriLyt region is large, almost 3,000 bp, making this replication origin considerably more complex than others, including those from other human beta herpesviruses. This region can be divided into Essential Region I, with a bidirectional

ppUL84:IE2-p86-responsive oriLyt promoter and a pyridine-rich Y-block,⁴⁴³ and Essential Region II, which includes an RNA–DNA hybrid structure⁴⁹⁵ and an adjacent RNA stem-loop structure capable of binding ppUL84.¹³⁰ This region is also rich in other direct and inverted repeat sequences and transcription factor-binding sites. Viral DNA destined for replication circularizes after being delivered to the nucleus, associating with ND10, sites of early transcription where DNA synthesis initiates following the successive localization of IE1-p72, IE2-p86, and ppUL84, then UL112-113 proteins and, finally, ppUL44, which brings in other replisome components. A distinct subregion containing viral DNA and replisome components eventually dominates the nucleus as a distinct replication compartment. Six herpesvirus core replication fork proteins compose the replisome that synthesizes DNA.⁴²⁴ In HCMV, this replisome composed of the UL54-encoded DNA polymerase catalytic subunit (POL) together with the UL44-encoded polymerase processivity subunit (POL:PPS complex), the UL57-encoded single-strand DNA binding protein (SSB), and the heterotrimeric helicase-primase (HP) consisting of UL105-encoded HP1, UL70-encoded HP2, and UL102-encoded HP3.

Initiation of DNA synthesis requires oriLyt promoter activity, which is dependent on a ppUL84:IE2-p86 complex. ppUL84, a DE gene long known to play a key role in this process,⁴⁴³ forms homomultimers and binds to IE2-p86, thereby antagonizing transactivation by this protein. Its role in viral DNA synthesis is highlighted by the phenotype of mutant viruses.⁴⁴³ In complex with all UL112-113 proteins,²⁹⁵ ppUL84, a putative DExH/D box protein⁴⁴³ recruits ppUL44/PPS.⁶³⁵ Interactions between these components must form to support viral replication.²⁹⁵ As such, oriLyt recognition by ppUL84 bridges to the replisome via PPS. In addition, cellular functions such as C-EBP²⁷⁷ and hnRNP-K²⁷⁸ associate with these complexes and are necessary for viral DNA synthesis. Genetic evidence strongly supports the role of a ppUL84:IE2-p86 complex in initiation of oriLyt-dependent viral DNA synthesis,⁴⁴³ although the lack of a cell-free system leaves other details to be investigated. Other HCMV IE genes pUL36/vICA, pUL37 \times 1/vMIA, ppIRS1, and ppTRS1 make the host cell environment more conducive to the process without being actively involved in the replication compartment.⁴⁴³

HCMV DNA synthesis may start as theta form before switching to a rolling circle mode of replication. The architecture of replicating DNA is consistent with concatemeric structures generated by rolling circle form of replication, and this is the likely template for the genome encapsidation. IE2-p86, ppUL84, and four UL112-113-encoded phosphoproteins (pp34, pp43, pp50, pp84) produced via alternative mRNA splicing⁷⁰⁷ all associate with prereplicative sites near ND10 sites in the nucleus to coordinate assembly of the viral replisome. Based on studies of viral mutants, all of these proteins must be simultaneously coexpressed to form a complex, colocalize with ND10, and recruit ppUL44/PPS to prereplication foci.²⁹⁵ It has long been appreciated that ppUL44/PPS and ppUL57/SSB show distinct nuclear localization patterns prior to the initiation of viral DNA synthesis, as the replication compartment forms around 19 hpi.⁴⁶⁷ Although IE2-p86 is believed to facilitate prereplication complex formation, it is the UL112-113 proteins that independently associate with ND10 and recruit the replisome to the viral genome, apparently via ppUL44/PPS.²⁹⁵ A shortage of UL112-113 gene products may underlie

the MOI-dependent replication defect in IE1-p72 mutant virus.²⁰⁵ The four UL112-113 gene products, ppUL84, IE2-p86, and six herpesvirus-conserved replisome proteins remain associated with the replication compartment throughout the remainder of infection.

Viral DNA synthesis is the target of antiviral drugs (foscarnet, ganciclovir/valganciclovir, and cidofovir) in current widespread use. Acyclovir/valacyclovir, although sometimes employed for HCMV prophylaxis, has no basis of action against HCMV due to the absence of a virus-encoded thymidine kinase. All of the effective anti-HCMV drugs act on or through the viral DNA POL. Intravenous ganciclovir and oral valganciclovir represent gold standards for prevention and treatment of HCMV infection and disease.^{188,596} Although active against other herpesviruses, these are rarely used outside of HCMV due to toxicity. Foscarnet inhibits viral DNA synthesis by binding the pyrophosphate release site similar to phosphonoacetate. Structure–function analysis has shown that foscarnet, like phosphonoacetate, inhibits POL enzymatic activity by maintaining a closed, untranslocated state on the viral DNA template.⁷³⁵ In cell culture, ganciclovir or foscarnet have proven to be excellent HCMV DNA synthesis inhibitors and are superior to phosphonoacetate, due to lower toxicity during the extended treatment periods necessary with HCMV. Ganciclovir (as well as valganciclovir, a pro-drug that is converted to ganciclovir in the body) is monophosphorylated by UL97 kinase, a viral protein kinase able to recognize this nucleoside.^{341,640} Phosphorylation of ganciclovir monophosphate is completed by host nucleoside kinases, and the triphosphate form is incorporated by POL and chain terminates viral DNA synthesis. UL97-independent phosphorylation and modest selectivity for POL over host cell DNA polymerases underlie ganciclovir/valganciclovir toxicity. Cidofovir, a nucleotide triphosphate analog that does not require UL97 phosphorylation, also causes chain termination, but POL is positioned differently on the template. Cidofovir is, like foscarnet, a second-line choice. As would be expected, clinical isolates exhibiting resistance to ganciclovir arise with mutations either in the protein kinase gene (UL97) or the DNA POL gene (UL54).

Additional anti-HCMV drugs are under development, and these will be mentioned here, although their targets lie outside DNA synthesis machinery. A terminase inhibitor AIC246 exhibits exquisite specificity for HCMV.³⁶⁸ The protein kinase, ppUL97 is a target of maribavir, for which difficulty was experienced in clinical development.³⁷³ Poor therapeutic effectiveness of maribavir may result from overlap in UL97 function with cyclin-dependent kinase (CDK) activity.^{246,494} The activity of maribavir varies dramatically with cell culture conditions.¹²⁰ The synergy observed between maribavir and CDK inhibition directly implicates overlapping function to sustain viral infection.²⁴⁶ Resistance to maribavir may be conferred by mutations in UL97 itself, as well as in UL27. Somewhat surprisingly, mutations in UL27 also develop spontaneously, as a UL97 mutant virus is propagated in the absence of drug,¹¹⁷ implicating UL27 influence on CDK activities during infection. UL27 directs the proteasomal degradation of histone acetyltransferase KAT5/Tip60,⁵¹⁸ leading to increased CDK inhibitor p21/Cip1. UL97 phosphorylates many targets in infected cells,⁴⁹⁴ including KAT5/Tip60, a modification proposed to increase viral gene expression.³³⁰ Compromised UL27 function may result in higher CDK activity that supplants the need for ppUL97 kinase.

Other HCMV DE gene products contribute to DNA synthesis as well as host DNA damage and ER stress responses. UL114-encoded uracil DNA glycosidase (UNG) and UL98-encoded nuclease (NUC) are core proteins that play poorly understood roles in viral DNA replication.³⁹⁹ UNG sponsors excision of uracil from DNA and control of DNA synthesis.^{496,503,633} The need for UNG, like UL97 kinase, is dependent on the cell culture conditions and cell cycle state. HCMV has a strong effect on DNA repair and the DNA damage response,^{203,354,502} and viral replication is compromised in ataxia telangiectasia-mutated (ATM) protein kinase-deficient cells due to the failure to upregulate H2AX-mediated stabilization of the MRE11-NBS1-RAD50 complex.⁷¹⁸ HCMV pUL35 associates with USP7 deubiquitinase as well as with components of the Cullen 4-DCAF1 E3 ubiquitin ligase complex and induces H2AX levels, thereby activating the DNA damage response.⁵⁴⁵ Therefore, pUL35, which is both a DE protein and a component of the tegument where it associates with pp71, is implicated in the modulation of the DNA damage response during infection. ER stress is also dramatically enhanced in HCMV-infected cells.^{20,87} UL38 modulates the ER stress response⁵⁰¹ and contributes to resistance of HCMV-infected cells to accumulating reactive oxygen species^{408,660} that can arise from activation of Mammalian Target of Rapamycin (mTORC)1⁴⁰⁷ as well as PKR-like ER kinase (PERK) pathways.⁷¹⁹ Therefore, the resistance of infected cells to ER stress,^{125,126} likely relies on pUL38, as well as pUL69, that together modulate the mRNA cap-binding complex so that it continues to function through the pUL38-imposed block.²² UL69 is a homolog of HSV-1 ICP27, which also exhibits translational regulatory activity. The most extensively studied aspect of pUL69, shared with ICP27, is its role in the transport of unspliced mRNA from nucleus to cytoplasm.³⁴⁰ UL69 binds RNA and interacts with the DExD/H-box RNA helicase UAP56 or the related URH49 protein, cell proteins involved in RNA transport.

Late Gene Regulation

Expression of HCMV L (γ) genes is maximal after viral DNA replication has begun. In fibroblasts, 24 hpi is typically designated as the dividing point between DE and L phase of replication. Leaky L (γ_1) genes are expressed even in the presence of viral DNA synthesis inhibitors, whereas true L (γ_2) expression is blocked by DNA synthesis inhibition. Observations that most L gene expression can continue even when viral DNA replication is inhibited and has kinetic subclasses were first made on HSV-1, and resulted in the use of γ instead of L. Leaky L (γ_1) and true L (γ_2) genes have very simple promoters defined by the region surrounding the TATA motif, although some have multiple transcription start sites. HCMV transcription at L times involves a considerable level of mRNA splicing and is symmetric off both DNA strands.²⁰⁴ Furthermore, the pattern of transcription and timing varies with cell type.⁶⁶⁸ In general, expression of DE genes continues during the L phase as L genes become active. Three HCMV true L genes have been studied in some detail: UL94, which encodes a tegument protein utilizing a single start site; UL99, which encodes tegument protein pp28, utilizes two separate start sites; and, UL75, encoding envelope gH. L40, a true L gene product encoded from a promoter element within the UL122 region, has been useful as a marker of true late gene expression. The promoter region required for authentic regulation of UL99, UL94, or UL75 is small and

poorly responsive to viral transactivators (IE1-p72, IE2-p86, TRS1) in transient assays. In the context of the viral genome, a UL99 promoter region containing little more than a TATA element and start site (−40 to +6 relative to the start site) is sufficient for regulated transcription, and a G:C-rich hairpin structure naturally present within the first 25 nt of the transcript regulates translation efficiency.²¹ Recently, the importance of specific late transactivators has come to light because “beta-gamma” genes in murine gamma herpesvirus 68 were shown to transactivate L genes promoters from that viral genome. Incisive studies of UL79, UL87, and UL95 control of HCMV true L gene expression^{264,471} revealed these essential genes to be necessary for UL99 and UL75 expression, as well as for the activation of a true late promoter element within UL44.²⁶⁴ An orchestrated L gene-specific complex may form through the association of UL79, UL87, and UL95 proteins with ppUL44/PPS in prereplication foci prior to the initiation of DNA synthesis.²⁶⁴

L gene products control capsid maturation, DNA encapsidation, virion and dense body maturation, and egress from the cell. By the L phase of infection, host cells have been subjected to substantial modification by viral gene products, with a large nuclear inclusion that contains replicating viral DNA and capsids as well as a cytoplasmic inclusion where final envelopment and egress from the cell take place. The balance of transcriptional and translational controls appears important throughout infection, as does the need to balance cellular metabolism and stress.

Capsid Assembly and DNA Encapsidation

The basic features of HCMV capsid assembly and DNA encapsidation^{80,653} are shared across the herpesviruses^{84,273} and evolved from those employed by the HK97 DNA bacteriophages,⁹⁹ including T4.⁵⁸ The process of virus maturation is orchestrated by protein–protein interactions employing common herpesvirus core functions and modified by viral and host enzymes, including protein kinases, proteases, and terminase (Table 62.1). Assembly begins in the nucleus where newly synthesized viral DNA is packaged into preformed capsids and concludes when nucleocapsids obtain an envelope at cytoplasmic membranes. The HCMV maturation machinery produces infectious virions as well as an abundance of noninfectious particles, all of which egress from infected cells by vesicular transport. Three capsid forms accumulate in the nucleus of herpesvirus-infected cells.²¹⁰ Two of these appear to be dead-ends: A capsids that lack both scaffold and packaged viral DNA; and B capsids that contain scaffold but lack viral DNA.^{84,99} The third form, C capsids, contains viral DNA in place of scaffold and probably represents nucleocapsids in the process of maturation. Tegument proteins are added to nucleocapsids sequentially starting in the nucleus and continuing in the cytoplasm, providing stability during nucleocapsid translocation from the nucleus to the cytoplasm and directing nucleocapsid trafficking to sites of envelopment in the cytoplasm.

The process of capsid formation begins when newly translated MCP associates with the maturational protease precursor complex (pPR-AP:pAP) and is transported into the nucleus.²¹⁰ Both pPR-AP, the UL80 gene product, and the assembly protein precursor (pAP), the UL80.5 gene product, are produced independently. The MCP:pPR-AP:pAP complexes are transported into the nucleus where proteolytic processing results in assembly into procapsid shells (Fig. 62.2).^{84,99,210} The maturational protease (PR) processes both pPR-AP and pPR in a

pathway that releases PR, pAP, and AP.²¹⁰ Although pAP is sufficient for procapsid assembly, self-cleavage of pPR-AP to PR and release of a number of pAP and pPR-AP products are required for proper DNA encapsidation and production of nucleocapsids. Precise protease cleavage steps lead to the release of MCP, inactivate the protease, and orchestrate the replacement of the scaffold in procapsids with viral DNA. PR and AP, as well as pAP forms, are completely removed from nucleocapsids into which DNA has been packaged. Properly formed nucleocapsids (C capsids) mature more efficiently than defective nucleocapsids such as scaffold-containing noninfectious enveloped particles (NIEPs).

The procapsid shell is made up of MCP-containing capsomeres, with six copies of MCP per hexon and five copies of MCP per penton. One of the 12 pentons in each capsid is composed entirely of PORT, the UL104 protein, a self-assembling homododecamer.²⁴⁸ The PORT penton provides a channel for viral DNA encapsidation. Triplex (TRI) complex TRI1:TRI2 is added to stabilize hexons and pentons,^{84,99} and SCP decorates the outer capsid surface, interacting with MCP at hexon tips. Based solely on predictions from HSV-1, a putative capsid vertex capping complex (CVC), composed of UL77 (CVC1) and UL93 (CVC2) proteins, decorates penton tips,¹³³ and the UL51 and UL52 proteins would be added to provide capsid stability. Available data on UL77, UL93, UL51, and UL52 mutant viruses^{73,212} predict such roles, although the order of addition of capsid vertex and stabilizing proteins remains to be established. In addition, it is not yet resolved whether these proteins are to be considered components of the capsid or tegument.^{84,99}

The preformed procapsids are made in the nucleus proximal to DNA replication compartments. Encapsidation of unit-length viral DNA genomes depends on a terminase (TER1:TER2) complex^{658,659} interacting with a specialized PORT penton. Terminase machinery recognizes free genomic ends and threads a single genome length of DNA through the PORT channel into each capsid. This process begins and ends at *pac* elements within terminal repeated *a* sequences, proceeding in a directional manner (S component first) on concatemeric DNA. A 129-bp region contains both *cis*-acting *pac* elements (*pac1* and *pac2*) and is sufficient to direct cleavage and packaging,⁷⁰² leaving single-base 3' extensions at both genomic ends. The packaging machinery of herpesviruses is analogous to distant evolutionary relatives, such as T4 bacteriophage.⁵⁸

Specific small molecule terminase inhibitors such as 2-bromo-5,6-dichloro-1-(β-D-ribofuranosyl)benzimidazole (BDCRB) have been exceptionally useful to synchronize viral infection to study maturation and egress steps.¹⁶ BDCRB, which interacts with the ppUL56:ppUL89 terminase, is chemically related to maribavir, the UL97 kinase inhibitor, although the two drugs act on different viral replication steps.¹⁸⁰ B capsids accumulate during BDCRB treatment of HCMV-infected cells but fail to encapsidate viral DNA after release of drug block, suggesting that DNA packaging machinery operates as capsids are assembled. The ATP binding site within ppUL56 and the nuclease site within ppUL89 contribute to activity. The nuclease site has a structure reminiscent of retroviral RNaseH-integrases and can be bound by integrase inhibitor.⁴²⁵ The antiviral drug candidate AIC246 apparently targets the ppUL56 terminase subunit.^{215,493}

Capsid localization, packaging, and cleavage of viral DNA are all regulated through phosphorylation. UL97 kinase (VPK) and cell cycle-regulated kinases overlap in function to support

viral replication.^{246,366,494} Once formed in the nucleus, nucleocapsids translocate to the cytoplasm.^{80,653} The most capsid-proximal major tegument protein in HCMV is the UL32 protein, pp150.⁷²⁹ pp150 is added to nucleocapsids in the nucleus^{548,651} and accompanies maturing particles to the cytoplasm. UL32 or UL96 mutant viruses accumulate nuclear pp150.^{651,652} pp150 and ppUL96 stabilize nucleocapsids in a common pathway of translocation to cytoplasmic sites of envelopment.⁶⁵²

Translocation, Envelopment, Egress, and Release

Virion maturation follows a two-stage envelopment and egress process that begins in the nucleus and finishes with virion release by exocytosis from the cell,^{80,653} depicted in Figure 62.2.

Nucleocapsid translocation from the nucleus to the cytoplasm is carried out by a herpesvirus-conserved nuclear egress complex (NEC), which carries out nucleocapsid translocation from the nucleus to the cytoplasm. The NEC is located at the inner nuclear membrane. This is probably one quality control step where preference is afforded to DNA-containing C capsids (nucleocapsids) over A or B capsids, possibly mediated by tegument proteins that associate with C capsids.^{80,653} The NEC is composed of a type II membrane-spanning component (NEC1, UL50 gene product) together with a nuclear lamina-interacting component (NEC2, UL53 gene product).³⁶⁶ These together facilitate egress from the nucleus by recruiting cellular and viral protein kinases to phosphorylate and disrupt the nuclear lamina cage and allow nucleocapsid passage. Consistent with this, NEC1 or NEC2 mutant viruses in many herpesviruses including MCMV and HCMV accumulate nucleocapsids (C capsids) in the nucleus. In HCMV, host protein kinase C functions interchangeably with viral ppUL97/VPK, cellular p32, and the lamin B receptor in the NEC to phosphorylate lamins.^{366,392} An HCMV-encoded nuclear rim-associated cytomegaloviral protein (RASCAL), the product of cORF-29, also interacts with ppUL50³⁹³ and may also contribute to NEC-dependent disruption of nuclear lamina. Following primary envelopment/de-envelopment, nucleocapsids are delivered to the cytoplasm with pp53/NEC2 remaining attached. ppUL53 accompanies the nucleocapsid as it is transported through the cytoplasm and becomes part of the tegument in mature virions. ppUL50/NEC1 remains in the nucleus and apparently cycles ppUL53. Together with MIE and replisome components, ppUL50 makes a sensitive indicator of nuclear contamination within purified virus particle preparations. Other cellular proteins, including BiP/GRP78, interact with ppUL50, and, together with dynein, contribute to nucleocapsid translocation⁸⁶ as well as the organization of the AC, although these pieces have not been entirely fit into a pathway.

Nucleocapsids most likely reach the cytoplasm by obtaining a temporary envelope at the inner nuclear membrane passage through the perinuclear space and de-envelopment at the outer nuclear membrane (Fig. 62.2). Once delivered to the cytoplasm, transport is directed to sites where tegumented nucleocapsids obtain a “second,” final envelope to become virions. This final envelopment occurs at ERGIC/endosomal/exosomal membranes based on lipid composition^{343,666} and results in formation of mature virus that is released from cells. Once formed, virions are translocated to the cell surface within small vesicles using cellular exocytic transport machinery. All of these important cytoplasmic steps in maturation, from tegumentation through release, are closely associated with the specialized AC. The AC consisting of a remodeled cellular

secretory apparatus that distorts the cell nucleus, resulting in a characteristic “kidney” shape while the cell takes on a characteristic “owl’s eye” appearance.²⁴⁷ In electron micrographs, virions and dense bodies can be seen concentrated within this region, some undergoing envelopment. Within the AC, the *cis*- and *trans*-Golgi network, ER, ERGIC, and endosomes are arranged into a compact nested and cylindrical array adjacent to the nucleus.^{143,144} Cellular markers for endosomal sorting and transport (ESCRT) and Rab GTPases localize to the AC together with viral structural proteins.^{80,653} Rab6, in particular, appears to facilitate maturation events in the AC.²⁶¹ The AC is a prominent feature of infected cells, the cytoplasmic inclusion nestled into a kidney-shaped nucleus. Although replication of all herpesviruses is thought to follow a similar pattern, the AC is a unique feature of beta herpesvirus-infected cells. In addition to virions, the AC supports maturation of many noninfectious particles, the most numerous of which are capsidless dense bodies that constitute about half of the mature particles produced. These form in the cytoplasm and follow envelopment and release steps similar to virions.^{80,653}

Tegument proteins associate with nucleocapsids in the cytoplasmic AC and facilitate envelopment. The AC is the principal location where final tegument components assemble on nucleocapsids and virions form. Envelopment produces mature, infectious virions within vesicles that are transported to the cell surface for release. Partially tegumented and partially enveloped nucleocapsids (often considered as being caught in the act) can also be observed in the AC. Infection with replication defective mutant viruses affecting UL71,^{557,716} UL94,⁴⁷⁵ UL96,⁶⁵² and UL99⁵⁷⁰ reveal greater proportions of tegumented nucleocapsids and partially enveloped particles. The UL99 gene product, tegument protein pp28 (a myristoylated and phosphorylated tegument protein), performs a key function in virion envelopment^{572,570} and acts through multimerization.⁵⁷¹ ppUL94, a binding partner of pp28,^{474,662} is involved at the same level as pp28 based on mutant virus phenotype.⁴⁷⁵ ppUL71 also controls the acquisition of the envelope,^{557,716} oligomerizing through a leucine zipper motif.³⁸⁸ Therefore, the emerging theme in directing acquisition of an envelope is protein–protein interactions, possibly in an oligomerization-driven process.

Other tegument proteins and envelope glycoproteins that localize to the AC have their major impact upstream or downstream of final envelopment. Virus lacking pp150, encoded by UL32, produces nuclear nucleocapsids that appear normal and deliver viral DNA to the cytoplasm but fall apart during this translocation, producing an AC that lacks recognizable capsids.⁶⁵¹ Therefore, pp150 is absolutely crucial for the maintenance of nucleocapsid stability during its translocation to the AC. pp150 may control further steps based on its interaction with bicaudal D1-Rab6 because this complex controls dynein-dependent vesicular trafficking.²⁶⁰ ppUL96 appears to cooperate with pp150 to stabilize nucleocapsids during translocation. A UL96 mutant also produces nucleocapsids that appear normal in the nucleus but become unstable in the cytoplasm.⁶⁵² Envelope glycoprotein gM, most likely together with gN, either contributes directly to secondary envelopment or helps organize the AC. The cytoplasmic domain of the multiple membrane-spanning gM interacts with FIP4-Rab11 complex to harness endosomal recycling and provide a platform for final envelopment to occur.³⁰⁸ UL100 mutants disrupting this domain are slow to form an AC and produce less infectious

virus due to defective final envelopment.³⁰⁷ The gN cytoplasmic domain is also crucial for this process,³⁵⁸ consistent with the need to assemble a gM:gN complex and in agreement with the colocalization of gM:gN with ESCRT components that are also involved in endosomal recycling. Most important, both VPS4A and CHMP1A components localize within the AC, with a striking colocalization of CHMP1A and assembled gM:gN.⁶⁵⁰ Using a series of dominant negative inhibitors, this study implicated CHMP1A ESCRT component and the ATPase VPS4A directly in final envelopment.

Once virions are enveloped, they are carried in vesicles to be released through exocytosis. This step carries virus particles as well as dense bodies to the extracellular space and is carried out by the cellular exocytic pathway. Surprisingly, HCMV is the first herpesvirus with evidence of a viral function that facilitates exocytosis of viral particles. UL103 mutant virus is defective in releasing virus to the extracellular space.¹⁶ Therefore, ppUL103 influences vesicle trafficking after envelopment to facilitate more efficient egress of fully enveloped virions and dense bodies out of the cell. These studies employed the DNA encapsidation inhibitor BDCRB to synchronize infection at late times, and showed that maturation and release is complete within about a day. Progeny virus is efficiently released from cells, reaching steady state levels where half of the infectivity at very late times postinfection is found in the culture fluid and half remains cytoplasm associated.

Effects on the Host Cell

Above and beyond the cellular changes that facilitate replication, presented in the rest of this section on replication, HCMV infection modulates cell-intrinsic host defense in three important ways: (1) altering pathogen recognition receptor signaling; (2) subverting cytokine and interferon activation to reduce the impact of cytokines and interferons; and (3) suppressing cell death to prevent or delay the premature demise of infected cells. As with other aspects of viral modulation of host defense, cell intrinsic pathways are dampened but not necessarily eliminated. Furthermore, modulation of intrinsic host defense develops along with the stages of the replication cycle, so it is sometimes difficult to distinguish a role in replication from a role in immunomodulation. Furthermore, HCMV dramatically stimulates cells through virus particle attachment-dependent^{131,262} as well as early gene expression-dependent pathways such that virus-infected cells to be cycling without proceeding into a true S phase as viral DNA synthesis and maturation take place, based on a variety of gene expression pattern analyses.^{371,550,707} Therefore, infection suppresses some cell signaling pathways, such as interferon activation, that limit viral replication, while stimulating others, such as cell cycle kinases, that benefit replication. As infection proceeds from the early phase to the late phase, a wide range of changes occur in conjunction with development of a dramatic cytopathology. Both a cytoplasmic AC and a nuclear replication compartment form as infection progresses along with a striking metabolic signature^{376,549,682,731} and increasing resistance to stress.^{377,378} A wide variety of viral gene products have been implicated in the control of cellular changes as well as in blocking pathways that become triggered (Table 62.1).

The impact of HCMV infection varies with both viral strain and cell type. Experiments with viral mutants together with either knock-down or knock-out cells or animal models facilitate the identification of viral functions and the cellular

pathways being targeted; such experiments have also revealed viral strain and strain variant differences in behavior.^{246,377,378} Significant effort has gone into the identification of HCMV gene functions that contribute to replication in a cell type-specific manner, distinguishing behavior in fibroblasts from behavior in epithelial, endothelial, macrophage, dendritic cell, and myeloid progenitors that are available as continuously propagated cell lines or cultured directly from human tissues. Even the most commonly studied fibroblast host cell type sometimes give diametrically opposed responses to viral infection depending on host cell variation, as revealed when UL97 function¹²⁰ or M45 function⁶⁷⁸ was assessed. Therefore, CMV infection sometimes unveils crucial host cell differences where none were suspected, such as the way RIP3 and DAI levels are known to control the susceptibility to virus-induced programmed necrosis.^{677,678} Viral strain variability is more complex, because CMV is known to undergo sequence drift during propagation in cell culture. To circumvent viral strain variability, efforts to employ low passage strains as well as to evaluate multiple viral strains for common properties have been paired with study of multiple cell types. This situation has become a particular concern where the impact of a viral gene product is subtle as well as in situations where no underlying mechanism is demonstrated. An eventual integrated understanding of the impact HCMV has on host cells will clearly depend on the generation of complementary data from different settings.

The orchestrated NF- κ B-dependent cytokine and IRF3 plus NF- κ B-dependent interferon responses that follow HCMV particle attachment and penetration leads to diverse host cell gene expression that includes features of growth factor activation and second messenger-type responses associated with calcium mobilization.^{131,262,734} This IFN-like response pattern predominates independent of virus strain or cell type, with NF- κ B activation following a two-phase pattern starting as early as 5 minutes after exposure to virus particles, which is followed up with a subsequent activation of this pathway around 24 hpi.^{131,262,734} This activation pattern is reminiscent of pathogen recognition receptor responses,⁵³⁷ where there is a primary response as well as a secondary response to factors like TNF and IFN that result from the primary response, and, in agreement with this, antiviral gene products are produced.^{131,262,573} DNA-dependent activator of interferon (DAI, also called ZBP1 and DLM-1) is a cytosolic DNA sensor that activates IRF3⁶⁴⁷ and NF- κ B²⁸¹ and has been implicated as the main pathogen recognition receptor in postattachment events that trigger virus particle-induced IFN response in fibroblasts.¹⁵³

Although dramatic, the IFN-like impact of HCMV on cells is dampened by input virion proteins as well as by additional viral gene products made during infection. Input pp65, the major tegument protein, localizes to the nucleus where it reduces activation of cytokines and IFN by input particles,³⁷¹ while itself being dispensable for replication. Input virion ppUL69, ppUL97, and pp71/ppUL82, all known for impacting viral gene expression, also modulate the host cell response to infection. In monocyte cell lines, a further damper on cytokine production is the UL7 gene product, a CD229-SLAM homolog expressed late in infection.¹⁷⁷ Viral proteins encoded shortly after infection, including the MIE gene products, IE1-p72 and IE2-p86, IE gene products from the UL36-UL37 locus, and a wide array of DE and L gene products modulate the host cell response to infection by sustaining cell viability as well as energy

production and metabolism. Host cell modulation by IE1-p72 involves formation of a complex with STAT1 and STAT2 to prevent association with IRF9, thereby dampening activation of IFN-responsive promoters.⁴⁵⁸ IE2-p86 contributes to down modulation of this response in ways that have not yet been distinguished from its overall repressive effect on cell viability.⁶⁵⁵ The pathogen recognition receptor DAI senses incoming viral DNA and triggers either an IFN-like response in HCMV infection¹⁵³ or, in MCMV, a RIP3-dependent cell necrotic death naturally suppressed by the virus.^{677,678} M45-encoded vIRA, a RIP homotypic interaction motif (RHIM) inhibitor, is an important suppressor expressed by MCMV^{508,676,677,678} that can also deflect NEMO-dependent NF- κ B signaling during infection.¹⁹¹ Whether HCMV encodes functions that modulate DAI-RIP3 death remains to be investigated. Therefore, initial contact of HCMV with cells triggers DAI activation of NF- κ B and IFN β ,¹⁵⁴ whereas MCMV completely suppresses this signaling in infected cells. In this way, necrotic cell death, apoptotic cell death, and the cytokine activation pathways are all tightly regulated as they have evolved to carry out cell-intrinsic host defense^{279,677,678} to eliminate virus-infected cells.⁴⁰⁵ As a result of studies on cytomegaloviruses, host defense pathways under the control of caspase 8 and RIP3 are becoming recognized as evolutionary adaptations to virus-encoded cell death suppressors.²⁸⁰

The cell cycle state at the time virus enters a cell is a crucial determinant that dictates whether infection is impeded or proceeds. Cell cycle is a factor in reactivation from latency as well. Permissive fibroblasts in G0 or G1 at the time of viral entry support IE gene expression and proceed into viral replication, but cells in S or G2 suppress IE gene expression, and, surprisingly independent of the ND10/PML-repression pathway,⁷⁴⁰ quite distinct from epigenetic control of viral gene expression in G0/G1 cells.⁷³⁹ Curiously, treatment with either cdk inhibitor or DNA damaging agents reverses this suppression, suggesting that there is a yet-to-be unveiled cdk/DNA repair-dependent pathway of regulation that can shut down virus at a pre-IE phase following entry.^{283,284,739,740} To support viral replication, cells must complete cell division and cycle back to G1 when IE gene expression occurs and replication proceeds.⁷⁰⁷

Once replication initiates in G0/G1 cells, input viral tegument proteins together with newly expressed IE proteins dysregulate normal cell cycle progression such that many cellular gene products associated with cell division are available to the virus, although cellular DNA synthesis is blocked.^{371,550,707} There is overlap in the impact of viral proteins on viral and host gene expression, as described in the section on replication. Virion VTA/pp71 induces resting cells into G1 phase by interacting with cellular Daxx and ATRX, thereby dampening PML-dependent repression of gene regulation.^{352,544,579} analogous to derepression of viral IE gene expression.^{579,628,629} Cellular genes responsive to pp71 may also respond to pathogen sensor signaling, stress, and/or autophagy.^{382,491} Virion-associated ppUL69, a herpesvirus-conserved multifunctional regulatory protein (MRP) that is similar to HSV-1 ICP27, is required to regulate gene expression as well as to inhibit cell cycle progression during infection, although the mechanisms remain to be established. Like HSV-1 ICP27, ppUL69 can bind RNA and shuttles between the cytoplasm and nucleus, thereby contributing to differential viral and cellular mRNA transport. Export of unspliced RNA in HCMV-infected cells involves the cellular DEXD/H-box (DEAD-box-related) RNA helicase UAP56,³⁴⁰

an aspect that appears distinct from HSV-1. Once infection begins, both IE1-p72 and IE2-p86 may alter cell cycle progression, although studies do not distinguish indirect impacts via regulation of other viral genes. IE2-p86, in particular, binds to p53, as well as other cell cycle-regulated proteins, and may influence cell cycle progression or orchestrate some activity of p53 and Cdks that drive the infected cell into a state that appears similar to actively cycling cells.^{257,628,629}

To successfully replicate in the host, HCMV must counteract cell death triggered by diverse insults arising from cell-intrinsic stress, pathogen sensors, TNF-family death receptors, and cytotoxic NK and CD8 T cells. The HCMV IE gene UL37 \times 1 encodes a mitochondrial inhibitor of apoptosis (vMIA)^{201,214,377,378} that is the most potent inhibitor of mitochondrial cytochrome *c* release known. vMIA naturally prolongs HCMV replication by defusing a programmed cell death pathway dependent on a mitochondrial resident serine protease, HtrA2.³⁸⁰ vMIA also dampens release of ER Ca⁺² stores.⁵⁷⁴ vMIA has two critical domains: an amino terminal hydrophobic membrane anchor that associates with lipid rafts in the ER^{712,713} to target the protein to the outer mitochondrial membrane, as well as an internal alpha helical antiapoptotic domain that binds and sequesters the Bcl2 homologs Bax and Bak as an oligomer.^{286,694} While blocking cytochrome *c* release, the impact of vMIA is to induce mitochondrial fission. In addition to Bax and/or Bak, this cell death suppressor must also engage growth arrest and DNA damage 45 (GADD45) and Bclx_L proteins via its antiapoptotic domain to prevent apoptosis.⁵⁹¹ This vMIA-dependent change blocks release of cytochrome *c* following induction of intrinsic or extrinsic apoptosis and prevents activation of executioner caspase 3.^{377,378} MCMV encodes two viral proteins, one (UL38.5-encoded vMIA) inhibits Bax activation^{377,378} and another (UL41.1-encoded viral inhibitor of Bak oligomerization [vIBO]) inhibits Bak oligomerization.^{91,363} Viruses with mutations in UL37x1 fail to encode a diverse family of differentially spliced UL37 gene products—most of which are glycosylated—that can all suppress cell death. Cells infected with UL37 \times 1 mutant viruses become more sensitive to inducers of caspase-dependent apoptosis³⁸⁰ and succumb to an HtrA2-dependent serine protease programmed death pathway that naturally terminates infection in fibroblasts.³⁸⁰ The amino terminal mitochondrial targeting domain (aa 5–34) and a carboxyl terminal antiapoptotic domain (aa 118–147) are together necessary and sufficient to block cell death induced in a wide variety of ways.²⁰¹ In addition to vMIA, a noncoding RNA, β 2.7 accumulates to very high levels during infection,²⁰⁴ and interacts with mitochondrial complex I to suppress apoptosis resulting from exposure to the respiration toxin rotenone as well as from cell stress.⁵¹³ β 2.7 RNA also prevents metabolic changes that are controlled at the mitochondrion.⁷³⁷ Neither β 2.7 nor vMIA is essential for viral replication in fibroblasts, although some viral strains are more or less dependent on these functions, possibly due to overlap in sustaining mitochondrial respiration through the very long HCMV replication cycle. Other viral gene products, including UL38, IE1, and IE2, contribute to cell death suppression³⁷⁸ in ways that may be related to their impact on gene expression.

Viral IE protein vICA inhibits caspase 8 activation in a manner analogous to cellular FLICE inhibitory protein (cFLIP) without exhibiting any obvious sequence similarity to cFLIP or any vFLIP. Like cFLIP_L, vICA prevents activation by

binding to the prodomain of procaspase-8, blocking both basal as well as TNF receptor-induced activity of this caspase.⁵⁸⁵ Therefore, vICA blocks extrinsic apoptosis induced by TNF family death receptors, but fails to block intrinsic cell death. vICA is one of the genes that becomes mutated in HCMV, as well as RhCMV, upon laboratory propagation, and this change increases susceptible to death receptor-induced apoptosis.⁵⁸⁵ In macrophages, vICA-deficient viruses induce premature apoptosis that cuts short replication even in the absence of inducers of extrinsic apoptosis.^{377,405} The other potent inhibitors of apoptosis such as vMIA and $\beta 2.7$ cannot rescue cells in these settings. The function of vICA is likely to counteract the consequences of death receptor TNFR1 upregulation mediated by UL138, an early gene product that is also latency-associated.^{321,406} In RhCMV, the nonfunctional UL36 homolog in the commonly used 68.1 strain³⁸¹ has little apparent effect on infection in macaques,^{237,238,240} suggesting that additional cell death suppressors are active. However, mutation of MCMV M36-encoded vICA, like HCMV UL36, results in premature apoptosis in mouse macrophages and attenuates virus replication in mice.¹²³ In MCMV, where viruses with a mutated M45 gene are severely attenuated,^{677,678} vICA inhibition of caspase 8 sensitizes cells to DAI-RIP3-mediated programmed necrotic host defense pathway.⁴⁰⁵ The predicted consequence of expression of vICA (together with vIRA) in MCMV assures that death receptor signaling is shunted toward cytokine activation and away from apoptosis or programmed necrosis. Therefore, evolution has left this cell death suppressor with different roles despite high conservation across primate and rodent CMVs.

Infection with HCMV and other herpesviruses results in production of double-stranded RNA (dsRNA), reaching high levels at late times during replication.²⁰⁴ Viral dsRNA, like dsDNA, triggers IFN activation via pathogen recognition receptors such as TLR3, which scores as an important receptor in MCMV infection.⁶⁴⁶ dsRNA also contributes to activation of proteins that mediate IFN-induced antiviral resistance, including protein kinase R (PKR) and 2'-5' oligoadenylate synthetase (OAS). If not suppressed by viral modulators, the pathogen recognition response and IFN effector pathways shut down protein translation in infected cells, prematurely terminating viral replication. HCMV encodes proteins that bind dsRNA to prevent activation of the PKR and OAS pathways. HCMV latency-associated gene product ORF94, a nucleolar protein, blocks OAS activation.⁶⁴⁸ In HCMV, either of the US22 family members, pIRS1 or pTRS1, modulates the interferon response within infected cells by blocking dsRNA-dependent activation of PKR or OAS as soon as these IE proteins accumulate during replication.^{116,370,371} Similarly, in MCMV, two US22 family members, m142 and m143, block PKR activation, although these function together as a complex.^{89,371}

PATHOGENESIS

HCMV infection in humans initiates when exposure to virus-infected body fluids overcomes innate immune barriers and sustains replication and dissemination. These events occur most frequently at mucosal sites. A systemic infection takes place where virus can be detected in PB leukocytes that are responsible for dissemination to salivary glands and kidneys. Depending on the age of the host, persistent shedding in saliva and urine

may proceed for months to years. HCMV is readily detected in body fluids during primary infection regardless of the immune status of the host or any disease pathogenesis. In immunocompromised individuals, HCMV may infect endothelial cells in addition to myelomonocytic cells at levels that may contribute to disease pathogenesis in the immunocompromised host. By far the most clinically useful virus-positive cell is the neutrophil, which forms the basis of the antigenemia test.²⁰⁸ Although viral antigen-positive neutrophils accumulate in relation to the intensity of the infection, the interaction represents an abortive infection, possibly due to the phagocytic properties of this leukocyte. Currently, virus is most commonly detected in body fluids and bloodstream by DNA PCR infection rather than by virus culture or antigenemia. Therefore, infection by any route culminates in a leukocyte-associated viremia that deposits virus in sites from which shedding can infect new hosts. When resolved through an effective cellular immune response, a latently infected myeloid cell population remains in the bone marrow precursors of monocytes, macrophages, and dendritic cells. This source of latently infected cells allows distribution throughout the body and contributes to the risk of transfer of HCMV with any tissue or organ during transplantation.

In contrast to the mucosal route that characterizes transmission in most of the human population, transmission during pregnancy involves the placenta,⁴⁶⁹ although the precise steps that gain access to the fetus are not yet established.³⁵⁹ Persistent and recurrent shedding in urine and saliva is more common in children than in adults.⁹³ Persistent shedding in urine contributes to transmission among children as well as from children to adults. Saliva is an important source in all age groups. In addition, breast milk transmission from mothers to children is important, but is only associated with a disease risk in low-birthweight newborns^{173,313} where viral inactivation methods are effective.²¹³ Finally, cervical or seminal secretions may contribute to transmission patterns in adults.⁶²²

HCMV is a classic opportunist such that disease pathogenesis follows either primary infection or reactivation from latency primarily when the immune response is compromised. The virus has long been known to reactivate and replicate to levels that cause pathology in the inflammatory environment set up by allogeneic tissue rejection; however, viral factors and mechanisms that underlie these viral properties remain to be characterized. Less well-appreciated is the fact that viral reactivation occurs frequently following trauma, surgery, and autografting, but disease appears to be rare in these settings,¹³⁴ suggesting that additional host factors contribute to disease pathogenesis in allogeneic transplant settings. Through their impact on cell intrinsic, innate and adaptive host defense pathways, virus-encoded immune modulatory gene products may represent important virulence determinants in disease pathogenesis. HCMV RhCMV, or MCMV each encode at least 100 gene products contributing to the host-pathogen interaction.

Due to strict species specificity, HCMV immunomodulatory gene products have been studied primarily in cell culture models. These have been complemented by some studies in animal models of infection, immunity, and disease pathogenesis. Many phenomena have been catalogued in both arenas but few concrete principles have emerged regarding the role of specific viral gene products or host pathways to disease. On the one hand, are differences in cultured cell systems that have been the focus of studies on HCMV mutant viruses, making

comparisons and generalization difficult. On the other hand, strain variability and adventitious mutations discussed above have complicated phenotypic studies with HCMV mutants. It is worth recounting that, despite the remarkable potency of unique immunostimulatory proteins encoded by HCMV US28 chemokine receptor,⁴²⁶ UL146/vCXCL1 chemokine,⁴⁶⁶ and UL111A/cmvIL-10 cytokine⁶⁰⁸ there is still remarkably little concrete understanding of how these properties contribute to outcomes during natural infection.

During infection, viral IL-10 is expressed in different forms, one (cmvIL-10) dominating productive replication and another (LAcmvIL-10) dominates latency in myeloid progenitors.⁵⁸⁸ These forms have subtle differences in their impact on T and B cells.⁶⁰⁷ Related cytomegaloviruses, such as MCMV or RhCMV, modulate host immunity and inflammation in ways that appear analogous to HCMV, but each of these surrogate viruses employs different mechanisms to achieve a common set of ends. Primate CMVs encode viral IL-10 and most closely related follow HCMV. All cytomegaloviruses engage myeloid lineage cells in the host as a component of dissemination during acute infection and as a site of latency during lifelong association with the host, although this may not be an exclusive relationship. The presence of latent virus in CD34+ and myeloid lineage progenitor cells^{403,510,515,580} likely gives rise to viral genome positive cells that distribute the latent viral reservoir throughout the host. Progenitors give rise to macrophages and myeloid dendritic cell lineages that take up residence in all tissues. A distribution of latent virus in monocyte-derived macrophages and dendritic cells remains the most likely explanation for virus transfer in high-risk SOT settings (seropositive donor organ into seronegative recipient), as predicted more than 40 years ago.^{704,705} Therefore, these specialized antigen-presenting cells very likely facilitate continued dissemination and distribution of latent virus throughout life while also being subjected to immunomodulation by viral gene products.^{403,510,515,580}

The potent immune modulators expressed by HCMV are likely to allow the virus to escape the full impact of immune clearance and to facilitate persistence.^{378,398,401,403} Modulatory functions are predicted to facilitate primary infection, contribute to efficient dissemination, and prolong replication. The adaptive T-cell response, which is less developed in children,⁶⁷¹ effectively controls active HCMV replication only after a prolonged period of time. This response must also contribute to maintenance of viral latency, either through suppression of reactivation, or, more likely, by preventing viral amplification following reactivation. T-cell immune deficit, such as occurs during AIDS, allogeneic HCT, following SOT, or during treatment with strongly T-cell suppressive lymphoma therapies leave patients open to HCMV infection and disease. Disease pathogenesis in these settings is widely believed to follow as a result of three collaborating events: (a) a proinflammatory cytokine-driven process that stimulates the latently infected cell to differentiate and reactivate latent virus to replicate; (b) immunosuppression that allows amplification via productive replication, either locally or systemically; and (c) direct or indirect viral or host immune-mediated damage that manifests as acute or chronic disease.²⁴⁷

Because of species specificity, study of HCMV in the context of a naturally infected host has remained largely unexplored. Animal models using available surrogate viruses such as MCMV or RhCMV, and cell culture models using HCMV, have been slow to dissect the basis of the virus–cell interactions

that underlie viral persistence in myeloid lineage cells of the bone marrow. An immature cell type where host epigenetic regulation of viral gene expression dominates has long been considered key to establishment and maintenance of latency, as a change in this repressive environment is key to reactivation and amplification as myeloid cells differentiate, particularly in an inflammatory environment.⁵¹² Current models of that focus on macrophages and dendritic cells have not yielded much evidence of viral control, save gene products such as UL138, LAcmvIL-10, and ORF94 that all have a primary effect as immunomodulators. Latency is crucial to the survival of HCMV in the immunocompetent host, yet, even the most scrupulous of models have only given rudimentary insights.⁵⁸⁸ Many preexisting expectations have been reinforced by these studies, but few of the biological details have emerged such that we still do not understand how HCMV remains for life in everyone who becomes infected.

Entry, Dissemination, Shedding, and Control in the Host

HCMV transmission patterns occur by direct contact, mainly as children acquire infection from parents and other children and then gradually throughout life.^{42,620} Age dependence of acquisition is linked to shedding patterns as well as hygiene.^{95,566} HCMV intrauterine transmission results in infection of approximately 1% of newborns, and is a worldwide concern.⁷²⁰ Child-to-child and adult-to-child transmission patterns are dependent upon virus shed in saliva, urine, and breast milk. Adult-to-adult transmission relies on sexual transmission. Virus is transferred by direct contact with secretions.^{93,621} Co-infection with multiple strains, reinfection with additional strains, changes in viral persistence, and reactivation of latent infection all likely contribute to transmission patterns. Adaptive T-cell immunity, in particular, maintains low viral levels, but this protection is not absolute, and, as discussed in the section on Immunity, the modulation by viral functions enables the virus to escape control. Consistent with this view, any other compromise to cellular immunity, in particular, contributes to the importance of this virus as a classic opportunist, whether it is congenital disease where the virus crosses the placenta to an environment where the immune system is not fully developed, or severe, life-threatening disease that follows immunodeficiency, immunotherapy, or immunosuppression.

Primary infection typically initiates with replication in mucosal epithelium at a portal of entry that follows direct contact with infectious secretions from another individual who either has a primary or recurrent infection. A high incidence of infection in certain populations and accumulating evidence that hand washing among caregivers prevents acquisition of HCMV from infants provide excellent evidence that this virus reaches a large proportion of the population through a direct route of transmission.⁹⁴ A systemic phase of infection depends upon a leukocyte-associated viremia that may be prolonged. Immature monocytes recruited from bone marrow (BM) seem to function as vehicles for viral dissemination, ferrying the salivary glands and kidneys, as well as other secretory organs, where the virus infects ductal epithelial cells, is shed and transmitted to new hosts. MCMV has provided key evidence for such a mode of dissemination as well as for the control of infection.¹⁴⁰ Dendritic cells together with NK cells produce cytokines that regulate development of adaptive immunity that is crucial for lifelong

host control of the virus. Neither HCMV nor MCMV can be detected cell-free in PB, although viral DNA in plasma is used to monitor the clinical status of immunocompromised individuals for active infection. Plasma viral DNA likely represents either viral genome fragments or encapsidated DNA that has been released from infected cells and tissues. This method of viral DNA detection is important in the assessment of immunocompromised hosts, along with assays for viral DNA, RNA, or antigen in PB neutrophils, mononuclear cells, and endothelial cells. This virus exhibits a relatively broad range of tropism for differentiated cells of various lineages when immune surveillance is compromised. Viral DNA is detected in PBMCs of long-term infected immunocompetent hosts, and has been used to identify latent reservoirs, but virus is not detected in plasma, neutrophils, or endothelial cells in immunocompetent individuals. The systemic phase of primary infection in adults is accompanied by the highest levels of persistent viral shedding in urine, saliva, breast milk, and genital secretions, and, as such may be the most important sources for transmission between hosts. The distribution of virus during acute infection has only been studied in the immunocompromised host, where a range of endothelial, epithelial, fibroblast, and hematopoietic cells in PB, BM, and tissues become infected. The involvement of these cell types in immunocompetent individuals is less well understood. Hematopoietic cells are likely to control dissemination⁵²⁴ and ductal epithelial cells are sites of viral production and shedding into bodily secretions. There is no direct evidence supporting a role for endothelial cells in primary infection or latency, although these cells are likely to play an important role in systemic infection that leads to a well-documented seeding of salivary gland and kidney tubule ductal epithelia. Viremia continues for a long period of time an adaptive immune response is first detected, typically lasting months in adults and years in young children. This prolonged period of primary infection is surprising given the intensity and quality of the host immune response, although this pattern reinforces the balance that characterizes the general picture of HCMV pathogenesis. An initial persistent infection is often observed, with gradual clearance of acute infection in immunocompetent individuals that correlates with an effective cell-mediated immune response rather than antibody levels. The relatively prolonged period of persistent shedding observed in infants correlates with their poor cellular immune response.⁶⁹¹

Immune Response and Modulation

Primary HCMV infection is brought under control by a combination of a coordinated innate and adaptive immune response. Much of what is considered to be important in the initiation of the immune response against HCMV comes from decades of immunological investigation of MCMV-infected mice.⁶⁹¹ Innate interferon and NK cell responses are important in the immediate control of viral infection, and, although monocyte-derived macrophages act as vehicles for dissemination and also regulate T-cell responses, they are not critical in innate clearance of MCMV.¹⁴⁰ Protective adaptive responses appear to be T-cell mediated, with antibody playing a secondary role in most settings, although important exceptions exist. Seropositive recipients of a HCMV-infected SOT are better able to control active viral infection and disease than seronegative recipients, and, concomitantly, seropositive donors of HCT provide better control of active viral infection than do seronegative donors in seropositive recipients. The severity of

disease due to primary HCMV infection in renal transplant patients is controlled through pretransplant immunization with the live-attenuated Towne strain of HCMV,⁴⁸³ which stimulates both antibody and cellular immunity.²⁶⁹

The natural immune response to HCMV has been characterized as very broad, strong, and durable, particularly with regard to the antiviral CD4 and CD8 T-cell frequency in the peripheral blood.^{57,268,644} The robust response and ease of detecting HCMV-specific CD4 and CD8 T cells has facilitated study of virus-specific immunity in humans.²⁶⁸ Despite robust T-cell and neutralizing antiviral antibody immunity, immune control of this virus is incomplete. Recurrence, reinfection, and shedding occur sporadically throughout life, particularly in pregnancy.^{96,566} The contrast between a robust immune response and incomplete control is often ascribed to the diversity of immune modulators encoded by HCMV and their effect on host defense.²⁶⁸ A high level of immune responsiveness is present years beyond primary infection at levels that exceed those of other herpesviruses or persistent viruses,⁶⁹¹ and the pattern of response to certain epitopes increases in an inflationary pattern that has been characterized in MCMV, RhCMV, and HCMV infection. Somewhat surprisingly, the high level of HCMV specific T cells in the periphery is not reflected in the lymph nodes,⁵¹⁹ which has been taken to indicate that this virus does not consume immunological attention to undermine responses to other pathogens. Although seropositive women occasionally transmit HCMV, the incidence of congenital disease in their offspring is less frequent and less severe than occurs in offspring of seronegative women with primary HCMV infection, indicating the value of immunity. Seropositive women who transmit virus transplacentally exhibit reduced antigen-specific T-cell proliferation,⁵²⁵ particularly in the quality of CD4 T-cell responses,³³⁵ as well as lower avidity IgG,³¹⁹ consistent with a role for adaptive immunity in protection from transmission. Transmission among children also results in a skewed CD4 T-cell response profile^{310,671} that may underlie prolonged shedding that contributes to both child-to-child and child-to-adult transmission patterns. Placenta contains virus in relatively high frequency and is associated with stillbirth.²⁶⁶ Transmission through the placenta⁴⁶⁹ and subsequent infection of the fetus may be blocked by neutralizing viral antibodies.^{359,431} Pooled human gammaglobulin, containing HCMV neutralizing antibodies, has been employed for prophylaxis as well as therapy in congenital disease settings.^{432,433} Lifelong HCMV infection has been associated with immunosenescence in the elderly.⁴⁶⁰ Despite susceptibility to reinfection, immunocompetent individuals can better control reinfection and avoid disease correlates following subcutaneous inoculation.⁴⁸³ Antiviral CD4 and CD8 T-cell immunity is crucial for lifelong control of infection and resistance to reinfection.^{268,714} In AIDS, successful anti-HIV therapy has reduced HCMV disease primarily as a result of increased level of HCMV-specific T cells.³³⁴

A characteristic feature of HCMV infection in the immunocompetent host is the persistence of active primary infection viremia, which is accompanied by virus excretion for months (adults) or even years (children) despite a fully functional immune response. The ability of this virus to avoid clearance by host immune mechanisms may be due in part to the many gene products that exhibit potential to interfere with the cellular or host response to infection. In excess of 40 HCMV gene products have been ascribed some role in modulating host systemic immune responses to viral infection, disrupting innate

immunity controlled by IFNs, chemokines, other cytokines or NK cells, and deflecting adaptive antibody or T cell-mediated immunity. Escape functions provide a balance to deflect host clearance and foster viral persistence and latency in immunocompetent hosts; however, the contribution of HCMV genes to pathogenesis and latency has remained elusive given the difficulty in identifying appropriate model systems.

Escape from cytotoxic T-lymphocyte responses is due to a nonrelated set of functions that prevent MHC class I antigen presentation with ER retention, proteasomal degradation, and peptide transport blockade by US2, US3, US6, and US11 gene products important in HCMV, and the generation of nonfunctional complexes, lysosomal degradation, and Golgi body retention by m04, m06, and m152 in MCMV. In addition to these mechanisms for interfering with MHC class I presentation, US2 gene product can cause degradation of MHC class II proteins, preventing their presentation of antigen, and the host CD4⁺ T lymphocyte response to HCMV MCMV m152 downregulates NK cell ligands in the RAE-1 family in addition to MHC class I. The extent to which some putative mechanisms of immune evasion are responsible for the persistence or virulence of HCMV infection is not yet clear. In some cases, the apparent mechanism of action of candidate immune escape functions remains unresolved, as with the HCMV-encoded MHC I homolog (UL18 gene product) initially suggested to play a role blocking NK cell activity through binding with killer inhibitory receptors but later shown to enhance NK cell killing of infected fibroblasts in a pattern that correlated with expression levels. More relevant contexts in which to test such potential immune escape functions are needed.

Natural Killer Cells

Extensive evidence from mice as well as supportive evidence from human infections shows that NK cells are the earliest immune cells to control levels of infection.^{268,685} This area of innate host defense, together with important consequences of viral modulation of NK cells, has developed to a remarkable level over the last several years, continuing to be led by incisive studies in mice.^{439,499,526} Remarkably, the antiviral NK cell response includes immune memory somewhat akin to T cells.^{439,641,642} The link between resistance to viral infection and NK cell function was first established in genetically deficient mouse strains, as well as in mice that were depleted of NK cells, infected with MCMV. Remarkably, certain strains of mice have a more effective NK response due to direct activation by a viral protein, encoded by m157,^{23,592} although an array of other MCMV and HCMV functions focus on impeding the NK response.^{268,439,526,641} NK-mediated strain differences in susceptibility mediated via MCMV m157 are dependent on direct binding to the activating NK cell receptor Ly49H, driving more efficient killing, associated with approximately 10-fold reduction in levels of virus early after infection. Despite the fact that m157 readily mutates under experimental selection and the activating receptor Ly49H is rare in wild mice, additional mouse and viral determinants with similar relationships have emerged and it now appears that a similarly remarkable phenomenon may accompany HCMV infection of humans.¹⁹² It is very clear that NK cells play an important role in host defense against HCMV, but in a complex pathogen-host relationship that is just becoming clarified.

Evidence supporting the importance of NK cells in defense against HCMV infection comes from the growing

numbers of viral gene products that block NK cell-mediated recognition as well as evidence that MHC class I down modulation by this virus makes cells more susceptible to NK lysis.²⁶⁸ A variety of host MHC interactions by viral MHC mimics and other interacting proteins have come to the fore as inhibitors of NK activity. In HCMV, the viral UL16, UL18, UL40, UL140, UL141, and UL142 proteins all play roles in NK cell down modulation, by downregulating activating ligands for NKG2D (UL16), by mimicking HLA class I (UL18) and interfacing with UL40,^{498,722} by binding to HLA-E (UL40) to retain NK repression via CD94:NKG2A,⁴⁹⁸ by downregulating the activating ligand CD155 (UL141) that is recognized by the activating receptor CD226,⁴⁹⁷ by retaining activating ligands in the Golgi (UL142),³¹ as well as by unknown mechanisms (UL140).^{268,709} MCMV encodes an evolutionarily distinct arsenal of NK-modulating functions.^{439,499,526}

Antibody

Experimental and clinical evidence indicate that humoral immunity to HCMV plays a role in protecting the host from disease, particularly in the setting of congenital disease.^{431,433} In mice or guinea pigs, passive or active immunization against a single envelope glycoprotein (gB) protects from challenge and disease. In humans, a subunit vaccine composed of gB in an adjuvant (MF59) was able to convey protection from infection in phase 2 studies,^{448,456} and certainly, maternally acquired antibody is an important determinant of protection from disease among very low birth weight newborns who acquire HCMV from mother's milk or blood products.¹⁷³

Many HCMV proteins are immunogenic such that nearly all immune human sera have both binding and neutralizing antibody to envelope glycoproteins gB (UL55) and gH (UL75), as well as binding antibody to a number of charged proteins such as the tegument phosphoprotein pp150 (UL32) as well as to a nonstructural DNA binding phosphoprotein, pp52 (UL44). Neutralizing antibody has been detected against principal envelope glycoproteins gB, gM:gN, gH:gL, and complexes formed between gH/gL and pUL128, pUL130, and pUL131A.³⁵⁶ Any of these antibodies may be associated with protection from infection and disease. It has become clear that assays for neutralization on fibroblasts underestimate the titers in human sera, such that low passage clinical isolates such as VR1814 infection of epithelial cells such as ARPE-19 cells shows significantly higher titers.^{356,542,697} Given that virus is largely cell associated in the host, but cell free in secretions, neutralizing antibody is likely to play an important role in controlling transmission. The extent to which humoral immunity from naturally acquired infection or from active immunization contributes to prevention of disease or reinfection remains to be fully elaborated.

HCMV encodes potent IgG Fc receptors from RL11, RL12, and UL118-UL119,⁶⁰⁹ and also incorporates bound antibody that facilitates entry into cells via Fc.³⁶¹ Few studies have been performed in animal models to provide guidance as to the significance of these activities during viral pathogenesis, although MCMV Fc receptor m138 is known to interact with B7-1 (CD80) and impact endosomal trafficking.⁶⁶³

Cell-Mediated Immunity

There is ample evidence supporting the crucial role of T-cell immunity in control of HCMV infection, perhaps none is more persuasive than the observation that severe HCMV disease is a

universal problem in patients with normal antibody levels who have profoundly impaired cell-mediated immunity, such as in recipients of allogeneic HCT or in AIDS. The severity of disease due to HCMV infection parallels the degree of T-cell impairment in AIDS as well as in solid organ transplantation and HCT, where adoptive reconstitution of T-cell immunity is effective.^{176,504} Understanding the adaptive T-cell immune response to HCMV infection, both in terms of the role of specific components of the immune response and specific viral proteins that are recognized, has been facilitated by the frequency of viral antigen-specific CD4 and CD8 T cells together with assays that assess responses to HCMV proteins and peptides. Investigations using murine models showed the central role of cytotoxic T-cell immunity in control of active viral disease as well as reactivation from latency and amplification. In humans, the T-cell response is broad and persistent and, in adoptive transfer experiments, CD8+ T cells with specificity for HCMV tegument proteins appear protective, although dependent upon the presence of CD4+ T cells in the transfer. Although a full description of adoptive immunotherapy to control of HCMV disease is beyond the scope here, evidence supporting a critical role for CD8+ T cells as cytotoxic effectors recognizing HCMV-infected targets as a component of immune clearance is incontrovertible.

The very convincing body of evidence that supports the role of cytotoxic T cells in host defense against HCMV infection is accompanied by a similarly extensive list of viral gene products that block T-cell recognition in either the MCMV model or in HCMV cell culture assays. Three MCMV gene products (m04, m06, and m152) modulate MHC class I. In HCMV, four glycoproteins (gpUS2, gpUS3, gpUS6, and gpUS11) down modulate cell surface expression of MHC class I proteins, all acting via posttranslational mechanisms²⁶⁸ that result in reduced immune surveillance rather than any impact on dendritic cell-dependent antigen presentation.⁵⁵⁸ US2 and US3 also effect MHC class II expression. The role of this class of immune modulator in surveillance is reflected in classic studies carried out in MCMV as well as more recent RhCMV studies.^{163,238} The viral UL18 MHC class I homolog is not subjected to down modulation due to an interaction with UL40.⁴⁹⁸ The novel MHC class I proteins expressed by cytотrophoblasts are not affected by these modulators, although US10 controls the levels of the novel HLA G, so may be important in modulation of fetal infection.⁴⁴⁴ All US2 and US6 family members are related to single immunoglobulin domain proteins that probably arose by duplication of an ancestral gene. US2 is most similar to US3, and US6 is most similar to US11. Mutants disrupting US2 to US11 completely fail to downregulate MHC class I expression in a number of cell types, including endothelial cells, epithelial cells, and dendritic cells.²⁶⁸ Any one of the four is sufficient to prevent translocation of MHC class I proteins to the cell surface, consistent with nonredundant roles. Although the activity of these proteins predicts a powerful role in escape from killing by cytotoxic T lymphocytes, thus far only limited evidence has shown that fibroblasts infected with a US2-US11 mutants are recognized and killed by a greater number of T-cell clones than are cells infected with wild-type virus. Upregulation of nonclassical MHC proteins such as MIC-A, which engages NKG2D on T cells as well as NK cells, may enable cytotoxic T cells to kill even though MHC class I levels are depressed by viral infection. In addition, HCMV retains the ability to down modulate MHC class I

expression even in the face of strong upregulation. Despite incisive mechanistic investigation in HCMV, a more complete evaluation of the physiological consequence of eliminating viral immunomodulatory gene products that block MHC class I expression has been possible with MCMV. Down modulation of MHC class I levels on MCMV-infected cells helps the virus avoid CD8 T-cell immune surveillance, but is not involved in altering T-cell memory set points.^{268,594}

A significant body of information has been generated studying US2, US3, US6, and US11. US3, an IE gene product, localizes to ER, possibly through interaction with calnexin, and down modulates tapasin-dependent peptide loading onto MHC class I proteins, thereby preventing egress to the Golgi. US2 and US11 encode DE gene products that degrade unassembled MHC class I via a Sec61 complex-dependent process and ubiquitin-dependent proteasome-mediated degradation. An immunoglobulin-like ER-luminal domain of gpUS2 is essential for binding to the $\alpha 3$ domain of MHC class I heavy chain, but requires the carboxyl terminus to direct degradation. Although gpUS2 and gpUS11 exhibit many of the same activities, gpUS2 binds more selectively to MHC class I haplotypes and MHC class II, whereas US11 gene product interacts with Derlin-1 and counteracts the misfolded protein response. US6 is expressed at late times and binds to the transporter of antigen processing (TAP) in the lumen of the ER and blocks TAP conformation in a manner that prevents ATP-dependent peptide transport. Although the US2-US11 appear to block effectively, the block can be overcome by certain T cells as well as in dendritic cells.

HCMV infection also down modulates constitutive MHC class II. gpUS2 and gpUS3, which modulate MHC class I levels, may also affect class II levels. Although the viral function remains to be identified, the principal MHC class II transcription factor, CT_{IIA}, is inhibited at early times of infection via enhanced degradation of Janus-activated kinase (JAK) with a resultant impact on JAK/STAT signaling that leads to CT_{IIA} expression. HCMV-encoded vIL-10 also exhibits an ability to reduce levels of MHC class II expression.

Interference with antigen presentation likely provides substantial benefit to the virus in the escape from clearance by CTL, but these functions do not abrogate the development of an effective CTL response. Viral functions that interfere with the level of T-cell responses are only beginning to be identified. In MCMV, one role of the viral chemokine is to recruit inflammatory monocytes from bone marrow that reduce the effectiveness of T-cell priming.¹⁴⁰ The balance of host and viral factors likely contributes to the level of viral persistence and the maintenance of latency in the host.

Persistence and Latency

As with all herpesviruses, HCMV latency is maintained in everyone who experiences primary infection. The universal risk of transplanting an organ or tissue from a CMV-seropositive donor to a CMV-seronegative recipient provides the most dramatic evidence of life-long infection, and propensity of virus to reactivate following immunosuppression or immunodeficiency is a central factor in HCMV-associated diseases. Most settings where HCMV disease occurs in immunocompromised hosts, such as SOT and allogeneic HCT recipients as well as in AIDS, are derived from reactivation. The earliest evidence of HCMV latency was the demonstration that leukocytes transmit HCMV infection despite the absence of infectious virus, resulting in the

current practice of leukodepletion that has dramatically reduced transfusion-acquired infection. Although evidence supporting HCMV latent infection has accumulated, the role of low-level persistent replication remains a topic of debate. Persistent replication occurs in epithelial cells of salivary glands and kidneys, with sporadic shedding in body fluids throughout life; whereas, hematopoietic progenitors harbor latent virus. Various myeloid progenitor cell types as well as the more differentiated cell lineages that arise from progenitors have been implicated in latency.^{510,515} Natural latency has been difficult to quantify beyond the identification of HCMV DNA-positive cells, along with occasional success at experimental reactivation from the natural latent reservoir. The balance between natural latency and reactivation is apparently controlled by cell type or cellular differentiation-specific factors that act at both genetic and epigenetic levels to restrict viral regulatory gene expression and replication.⁵¹² Considerable evidence suggests that viral genes fall under cellular control during latency. The MIE genes, IE1 and IE2, are repressed via the transcriptional enhancer and activated possibly as a result of cytokine or viral activation of transcription factors such as NF- κ B. Therefore, HCMV latency and reactivation seem to be controlled by host cell gene repression and activation that may be tied to differentiation signals that may be influenced by the cytokine and growth factor environment. Differentiation and activation of myeloid cells by proinflammatory cytokines that drive cell maturation continue to be considered important signals for viral reactivation.²⁵¹ These have also been observed using MCMV. This type of environment results from allograft rejection where HCMV has long been a prominent pathogen causing both acute and chronic disease. The maintenance of the viral genome appears to be limited to mononuclear myeloid progenitors that reside in BM,⁵⁸⁹ in cells that are as primitive as CD34+, lineage marker negative stem cells and as mature as monocyte-derived macrophages⁶⁰⁰ and DCs.⁵¹⁴ Virus reactivation occurs in mature cells. Myeloid lineages distribute widely as tissue resident macrophages and dendritic cells, suggesting they are the source of virus transmission in organ transplantation as well as dissemination within the infected individual. Neither granulocytes nor lymphocytes retain the HCMV genome and are unlikely to contribute as vehicles of virus dissemination.

The differentiation state of macrophages or dendritic cells, influenced by the proinflammatory cytokine environment and the level to which viral replication functions are encoded, has been associated with different outcomes, including restriction of viral replication with viral genome maintenance (latency), failure to support viral genome maintenance, and support of productive replication associated with reactivation.^{251,512,515} Latency in hematopoietic progenitor cells is considered an important biological reservoir, where reactivation is viewed as the first step in viral disease pathogenesis during transplantation or AIDS and may also underlie recurrent transplacental transmission as well as reseeding of epithelial cells that support sporadic shedding throughout life.

As a species-specific virus, HCMV does not infect any laboratory animal model. The species restriction results in a postpenetration failure in replication following IE gene expression before viral DNA replication and may be related to induction of cell death.⁸⁵ Experimental work on HCMV latency and reactivation employs both primary and continuous human cell culture models, with investigators selecting cell types suspected

of playing an important role in the naturally infected host. Considerable effort over the last 15 years has been focused on PB monocyte-macrophages,⁶⁰⁰ myeloid progenitors,⁵⁸⁸ and dendritic cells,^{251,514} all pointing to an important contribution of progenitors derived from BM in latency. Initially, focus on PB monocytes followed the demonstration that these cells harbor viral DNA but not infectious virus in healthy, HCMV seropositive individuals. Experimental models of latency have consistently shown the maintenance of the viral genome in a nonproductive state, with evidence of circular forms, and the ability to drive reactivation and replication through cellular differentiation pathways.^{512,515} One important study showed detection of viral DNA in naturally infected monocyte preparations that reactivated when differentiated into monocyte-derived macrophages under conditions that recapitulated allogeneic rejection,⁶⁰⁰ although triggering reactivation has proven to be one of the most elusive and poorly reproducible assays. Attempts to further investigate quantitative or qualitative properties of this natural latent reservoir have not succeeded and have been further complicated by the very low frequency of HCMV DNA positive monocytes in PBMC from healthy seropositive individuals. Therefore, even though there is little question that seropositive individuals are latently infected and sometimes have DNA-positive PB monocytes, variability apparently comes into play in determining the frequency of HCMV DNA positive cells in the PB of seropositive individuals at any particular time. Despite this, BM-derived or G-CSF mobilized PB mononuclear cells from seropositive donors contain viral genome positive cells at frequencies ranging from 10^{-4} to 10^{-5} with 2 to 15 HCMV genome equivalents per cell.⁵⁸⁹ These natural levels are consistent with cell culture models and implicate these cells as a reservoir of latency. Recent observations on reactivation using naturally infected progenitors further support the importance of primitive cells as a reservoir.^{46,510,515,580,588} Experimental infection of total progenitors, including CD34+-enriched cell populations, has been carried out with fetal liver, cord blood, adult BM, or G-CSF mobilized adult PB and each of these results in a quiescent infection appearing to reflect latency. Naturally infected BM-derived progenitors express unique transcripts, and these have been characterized as candidate HCMV latency-associated transcripts when also detected in natural latency.⁴⁶ Experimental infection of cultured CD34+CD38- progenitors is associated with a gradual shutdown in viral gene expression along with a sustained presence of a range of viral transcripts, including candidate latent transcripts. In addition to LUNA,⁴⁶ whose function remains unknown, three functional latent gene products have been elucidated: LAcvIL-10, expressed in latently infected myelomonocytic progenitors⁵⁸⁸; UL138, an inducer of TNFR1 expression^{321,406}; and ORF94, a 2'-5' OAS inhibitor.⁶⁴⁸

In addition to cell culture models of HCMV tissue tropism and latency, surrogate animal models of latency have been investigated to varying levels. Surrogates such as MCMV have continued to play a crucial role in understanding the overriding principles of viral pathogenesis and latency both because of the close biological relatedness and because of the array of mutant strains of mice that facilitate mechanistic studies affecting cellular and immune pathways common to rodents and humans. Therefore, MCMV recapitulates the general processes of latency and reactivation, providing insights into the distribution and type of cells that carry viral DNA, express viral

RNA, and reactivate as well as evidence that the cytokine environment necessary to observe reactivation is highly inflammatory and is influenced directly by TNF levels. The regulation of the HCMV major IE gene by TNF is well-established, and, together with UL138 function, suggests that TNFR1 may be crucial to natural latency and reactivation. Finally, interest in immune control of MCMV latency has suggested a direct role of CD8+ T lymphocytes independent of CD4+ T lymphocytes, B lymphocytes, or antibody, consistent with what is known about HCMV latency and reactivation following allogeneic HCT.

Although immunocompetent individuals eventually control primary infection through a strong and broad T lymphocyte response, persistent shedding of free virus in saliva, urine, and other bodily secretions continues for months or years and this is followed by intermittent asymptomatic reactivation and shedding in a proportion of healthy individuals. HCMV DNA is detected in a small proportion of the general population in saliva or urine and therefore virus must either reside in these sites, or be sporadically reseeded from a latent reservoir, possibly reseeded from a myeloid reservoir. Even in settings where disease occurs: (a) immunocompromised individuals where disease may result from primary as well as recurrent/reactivated infection, and (b) transplacental transmission during pregnancy where primary infection of the fetus arises from either primary or reactivated infection in pregnant women, the contribution of latently infected myeloid cell lineage cells is apparently critical to HCMV pathogenesis.

A full understanding of HCMV functions involved in the control of latency and reactivation will require the continued pursuit of appropriate cell-based and reconstituted animal-based models. In such settings, viral mutants that show little effect on productive replication can be evaluated for behavior and phenotype during latency, and host cell functions that contribute to either repression or activation of viral gene expression can be identified. Surrogate systems, including MCMV infection of the natural mouse host and RhCMV in monkeys will continue to provide complementary information.

EPIDEMIOLOGY OF HCMV INFECTION

Prevalence and Demographics

HCMV is universally distributed among human populations.⁹⁶ Table 62.3 lists data on prevalence of infection in women of childbearing age from Europe, North and South America, Africa, and Asia based on selected studies. HCMV epidemiology has focused on this population because of the public health importance of primary infection during pregnancy. Studies including both sexes consistently report prevalence rates that are slightly higher in women than in men.^{42,242,620} Although prevalence of infection increases with age in every group that has been studied, the overall prevalence of infection and the age at initial acquisition of virus vary greatly according to living circumstances. In general, prevalence of infection is greater and virus is acquired earlier in life in developing countries compared to the United States and Europe, where prevalence is greater in the lower socioeconomic strata, among nonwhites, and in immigrant populations from developing countries.^{96,220,225,620} Although prevalence is higher in nonwhite compared to white populations, these differences reflect exposure frequency related to living circumstances rather than to

TABLE 62.3 Prevalence of CMV Infection Among Women of Childbearing Age

Study location, date	Population	N	Prevalence (%)
Ankara, Turkey	Women 15–49 years	745	99
Cotonou, Benin	Pregnant women	211	97
Seoul, South Korea	Prenatal clinic	575	96
Sendai, Japan	Prenatal clinic	10,218	95
Sao Paulo, Brazil	Pregnant women, middle SES	427	67
	Pregnant women, lower SES	179	84
Northern Italy	Women, pregnant or hospital patients	12,568	77
Helsinki, Finland	Women, prenatal clinics	1,088	71
Birmingham, USA	Prenatal, middle SES	12,140	54
	Prenatal, lower SES	4,078	77
Grenoble, France	Women, prenatal clinic	1,018	52

racial factors. Infection reaches a majority of the adult population worldwide, although neither seasonal variation nor epidemics have been observed. Very high rates of transmission that occur in settings such as care of young children can be reduced through hygienic measures, including handwashing.

Seroepidemiologic studies of HCMV infection have largely relied on convenience samples, including patients at a particular health care institution, healthy blood donors, or hospital employees. Population-based estimates of HCMV prevalence have been derived from the National Health and Nutrition Examination Survey (NHANES), starting with a 1988 to 1994 set and continuing with 1999 to 2004 set (6 years of age or older).^{42,620} Based on these large samplings, the overall age-adjusted prevalence of HCMV infection in the United States remains about 59%, with about one-half of the U.S. population aged 6 to 49 infected.^{42,620} The age-related prevalence of HCMV infection derived from NHANES 1988 to 1994 is shown in Figure 62.4. More female patients (63.5%) than male (54.1%), and more non-Hispanic blacks (75.8%) as well as Mexican Americans (81.7%) than non-Hispanic whites (51.2%) were infected. Other than ethnic and racial correlates, multivariate analysis revealed that fewer years of education, residence in the South, larger family size, birth outside the United States, and government-provided health insurance (Medicaid) were also associated with higher seroprevalence, all factors related to socioeconomic status as well as living circumstances. Overall, the 1988 to 1994 results were similar to data from a more recent, 1999 to 2004 study period, with the important recognition of household income as an independent inverse risk factor for HCMV infection.⁴² The precise activities of lower socioeconomic groups that contribute to transmission have not been identified, but it is notable that long-term longitudinal studies in The Netherlands and Denmark have revealed that the greatest risk of HCMV infection in developed countries is associated with the childhood years,⁴¹⁰ and studies seeking to understand

FIGURE 62.4. CMV seroprevalence in the United States by age and race. (Reprinted from Staras SA, Dollard SC, Radford KW, et al. Seroprevalence of cytomegalovirus infection in the United States, 1988–1994. *Clin Infect Dis.* 2006;43(9):1143–1151, with permission from Oxford University Press.)

risk of primary infection during pregnancy consistently reveal that exposure to the urine and saliva of young children is a highly significant risk.^{95,259} Table 62.4 lists rates of HCMV seroconversion for various groups, including childcare providers, parents of young children, and patients attending a sexually transmitted disease clinic. Two types of exposures have consistently been linked with horizontal transmission of HCMV: contact with saliva and urine from young children and sexual activity in adults. The extended, multi-year pattern of shedding in children results from slow development of a virus-specific CD4 T-cell response,^{114,209,671} providing an ample source for transmission, with exposure to children the most dominant risk for seroconversion in susceptible adults.^{196,259}

TABLE 62.4 Incidence of CMV Infection in Various Groups

Group	Rate
Blood donors	1.57
Hospital employees	
Richmond, VA	2
Birmingham, AL	2.2
Pregnant women	
Middle income	2.5
Low income	6.8
Women in STD clinic	37
Adolescent females	13.8
Parents of CMV shedding child	
0–12 months old	47
≤18 months old	32
19 months–6 years	13
Daycare workers	7.920

Rate is percent per year that seroconverted from antibody negative to antibody positive.

Maternal Transmission Patterns

HCMV stands out among the human herpesviruses in patterns of intrauterine transmission across the placenta that result in infection of the fetus during pregnancy.⁴⁶⁸ Overall, maternal transmission occurs during pregnancy, where infection is associated with congenital disease, as well as at birth (intrapartum) or following birth, where disease is uncommon. Breastfeeding is the most frequent route of maternal transmission, but transplacental transmission is the most medically important. Intrauterine transmission of HCMV occurs in women who have already been infected before conception as well as in women who experience primary infection during pregnancy.⁶¹¹ Transplacental transmission in seropositive women that results in congenital infection is termed *recurrent infection* to acknowledge a likely contribution of reinfection, persistent infection, and reactivation of latent virus in this setting. Although pre-existing natural immunity reduces the risk of intrauterine transmission below the frequencies observed in primary maternal infection, estimates of this benefit¹⁹⁴ have been complicated by the difficulty of assessing recurrent infection directly in seropositive populations.^{70,720} The role of recurrent maternal infection as a source of fetal infection was initially suggested by the occurrence of congenital infection in consecutive offspring of the same mother and was confirmed by a cohort study where the rate of congenital infection in offspring of seropositive women was relatively high.⁶¹⁵ In addition, high rates of congenital infection occur in populations with near universal acquisition of virus before sexual maturity, including Brazil, where these rates are higher in seropositive populations than in HCMV-naïve populations.^{423,567,614} A proportion of congenital disease following recurrent infection results from reinfection with different strains based on serologic response characteristics.^{70,720} Although the most severe CNS damage follows primary gestational infection in naïve women, particularly early in pregnancy, maternal infection is a worldwide problem^{15,66,100,195,612,613} given high seroprevalence rates in

women of childbearing potential.^{720,721} Transplacental transmission is less frequent earlier in gestation and more frequent later, similar to other causes of congenital infection. Higher rates of congenital disease are associated with earlier transmission. A small cohort study of primary infections during the third trimester of pregnancy reported a transmission rate of 75%, without observing congenital disease in any of the 20 infected newborns.²¹¹

Newborns with congenital infection shed virus in urine and saliva at birth. Between 0.3% and 1.3% of newborns shed HCMV at birth based on a review of studies of 800 or more children in industrialized countries.¹⁶² Higher rates of congenital infection, from 2% to around 4% have been reported in developing countries.^{288,423,567} In the United States, the overall rate of primary maternal infection during pregnancy varies from less than 0.5% to around 4%, with higher rates occurring in young, unmarried women of lower socioeconomic status.⁶¹⁴ Intrauterine transmission reaches high frequency in confirmed primary maternal infection, with overall rates of approximately 33% congenital infection,²⁸⁹ based on a review of studies from many highly developed countries around the world. Importantly, newborns with HCMV in urine or saliva up to 3 weeks of age acquired the virus during gestation, whereas newborns remaining negative for this period that start to shed virus at around 6 weeks of age acquired the virus during or following birth.

Intrapartum and postnatal mother-to-child transmission follow maternal shedding patterns. Approximately 10% of women shed HCMV from the vagina or cervix; near the time of delivery, rates of 2% to 28% have been reported,⁶¹⁴ with the higher rates in younger women.³⁰⁰ If the newborn comes into contact with virus in the genital tract at the time of delivery, the rate of transmission is approximately 50%.⁵²⁷ Although intrapartum exposure contributes to the proportion of infected children, the most common route of mother-to-infant transmission is via breastfeeding. Studies detecting viral DNA by PCR found evidence of shedding in more than 95% of milk samples from seropositive mothers,^{30,249,272,688} extending earlier studies that employed virus isolation. Shedding follows primary or recurrent maternal infection, with no evidence of ongoing systemic infection because blood remains virus negative.²³² Transmission to infants of seropositive mothers is related to duration of nursing such that infection occurs in infants nursed for more than one month but not in infants nursed for less than one month.¹⁷⁰ A large proportion (69%) of infants acquire HCMV when nursed by shedding mothers, compared with only 10% of infants nursed by nonshedding seropositive mothers. Shedding peaks within the first few months and then declines. When studied, 70% of milk samples between 9 days and 3 months postpartum were virus positive, whereas samples were negative at other times.¹⁴ HCMV DNA PCR appears more sensitive than virus culture for detecting virus in milk,²³² and presence of either indicator correlates with transmission.

Neither intrapartum nor breast milk transmission of HCMV is associated with morbidity, except in very low birth weight premature newborn infants. Both routes are important in the epidemiology of infection. The proportion of infants who acquire virus during the first year of life is directly related to the prevalence of maternal infection and the proportion of mothers who nurse their infants.^{395,616} In countries where HCMV infection is universal and breastfeeding is common, around 50% of infants acquire virus before one year of age. In the United States,

this level is much lower. Young infants who acquire virus from a maternal source usually shed for years and become important sources for virus transmission to other children.

Horizontal Transmission

HCMV generally transmits most efficiently in settings where susceptible individuals are exposed to body fluids from individuals shedding virus, either by direct contact or contact with objects that have been recently contaminated with infected body fluids such as saliva and urine. Transmission on dry surfaces, by the airborne route or by aerosols, is not known to occur.⁶³² Following initial acquisition of HCMV, virus replicates and causes a systemic infection, sometimes detected as a leukocyte-associated viremia, and disseminates to infect tubular epithelial cells of secretory organs such as salivary glands and kidney where replication produces virus found in secretions. Not surprisingly, rates of infection are increased in any setting with a risk of exposure to infected body fluids. Child-to-child and child-to-adult transmission occurs in home and daycare, patterns that are reduced by frequent handwashing.⁹⁵ Virus may be shed in any body fluid, including urine, saliva, tears, semen, and cervical secretions, and persistent shedding may continue for months to years, depending on age and immune status of the host. The shedding period is longer in children than in adults, but clinically apparent disease rarely accompanies infection in immunocompetent populations. After resolution of primary infection, virus is shed sporadically for life.

Spread occurs frequently where young children congregate and interact.⁴⁴⁹ Cohort studies indicate that children in certain daycare centers frequently transmit virus to each other, whereas other centers have very low transmission rates.^{6,414,452} Young children shed virus in saliva and urine for long periods of time, providing ample opportunity for continued spread to classmates, parents, and daycare providers. Transmission in this setting is enhanced by frequent mouthing of hands and toys that become contaminated with virus,^{97,256} contributing to the exchange of body fluids with other children and adults. Childcare providers have markedly higher risk of acquisition directly related to the proportion of children shedding virus. This has been reported to be 7% to 20% per year in selected sites,^{7,193,415,451} although in the general population, acquisition varies dramatically such that family size emerges as the only correlate of seropositivity.⁶²¹ Rates are higher overall in parents of children than in similar aged adults not exposed to children.¹⁹⁶ Therefore, adults caring for young children in groups at increased risk for infection in families with multiple siblings,⁶²¹ home daycare,⁴⁰ or large daycare centers may all be at greater risk of infection proportional to the levels of shedding by children. Consistent with these patterns, parents of premature babies who acquire this virus nosocomially while in the hospital nursery are at risk of becoming infected.^{8,453,724} Overall, risk of infection is highly correlated with the presence of children who shed; a seroconversion rate of 45% per year was found in parents of toddlers who shed virus compared with 0% among parents of nonshedders.⁴⁵³ Restriction enzyme analysis of viral DNA has confirmed viral strain transmission from child-to-child, child-to-parent, and child-to-daycare provider.^{8,9,454}

Transmission also occurs between adults, and this mode predominates in sexually active populations.²⁵⁹ In adults, where sporadic shedding in saliva, tears, cervicovaginal secretions, and semen occurs, intimate contact is important for transmission.²³¹ Shedding patterns in saliva range from about 7% in healthy

seropositive adults to over 20%⁹⁵ in adult populations with greater numbers of sexual partners and those with other sexually transmitted diseases.^{110,135,259,470,601} A high incidence of infection has been reported in sexually active adolescents,⁶¹⁸ a population where contact with young children is a confounder.⁶²² Importantly, sexual transmission predominates in married adults without children where one partner is HCMV seropositive.¹⁹⁶ The similar DNA restriction enzyme digest patterns observed in viral strains from partners confirmed person-to-person transmission.²³⁶ Studies of hospitalized patients have shown virus may be frequently shed in urine or saliva,⁴⁵⁵ related to both immune status and trauma,¹³⁴ although hospital workers are not at increased risk of infection. The lack of evidence for increased risk of HCMV transmission to hospital workers provided the first evidence that good hygiene and infection control procedures (e.g., handwashing and avoiding contact with body fluids) can effectively interrupt HCMV horizontal transmission.

Horizontal transmission accompanies blood transfusion as well as transplantation of cells, tissues, or solid organs from seropositive donors. Universal screening has reduced the risk of acquisition from the blood supply in many areas of the world, including the United States and Europe. Transmission continues to be associated with transplantation and is clinically important as discussed below.

Molecular Epidemiology

The large size of the HCMV genome and the presence of genes with substantial interstrain variability have facilitated the characterization of viral isolates based on genetic differences by restriction fragment length polymorphism (RFLP) of entire genome as well as by comparing amplified viral DNA segments representing variable regions or genes such as the gB/UL55, and, more recently, gN/UL73 and UL144.^{24,479} All of these approaches are based on the general premise that epidemiologically linked isolates share nucleotide sequence identity and, conversely, isolates that are not epidemiologically related exhibit sequence diversity. Molecular genotyping of viral isolates has provided evidence for the following: vertical transmission of reactivated endogenous virus,²⁵⁰ transmission from child-to-child and child-to-parent,⁸ as well as to childcare providers,⁷ from child-to-mother-to-fetus,^{416,454} between newborns in a hospital nursery,⁶⁰⁶ and from organs in transplant recipients.¹²¹ In some cases, these genotyping tools have also discounted spread from a suspected source.^{10,726} Viral strains can be distinguished (by RFLP, sequencing hypervariable regions or other methods) such that multiple strains shed from different body sites as well as sequential detection of a different strain in the same person supports multiple infection even in immunocompetent individuals. The assumption that primary HCMV infection involves a single, genetically homogeneous strain has been drawn into question. Although studies based on genotyping or specific genes sequences obtained shortly after primary infection support the prevalence of a single strain in most settings,^{218,420,521} recent studies that employ deep DNA sequencing have revealed a high degree of genome wide variability within the host. These new methods raise questions about strain definition and heterogeneity^{216,217,520} and predict a bottleneck in transmission that is reminiscent of RNA viruses. Nevertheless, multiple infection occurs, based on detection of more than one genetically distinct strains in the same person has been reported in immunocompromised patients,^{165,322} healthy children,³⁹ sexually active women,¹⁰⁹ and mothers of newborns with congenital infection.⁷⁰

Although few studies have been carried out, one viral genotype has not predominated in a particular geographic location. A comparison of 223 strains from around the world did not associate gN genotype with geographic origin,⁴⁷⁸ and, studies of gB genotypes from various locations in Europe, North America, and Asia have not revealed associations.^{25,38,420,476,477,649}

CLINICAL FEATURES

Acquired Infection in the Immunocompetent Host

As a rule, infection with HCMV in the immunologically normal host is clinically silent.⁴⁴⁷ HCMV symptomatic infection occasionally results in a febrile, mononucleosis-like illness. More serious disease or systemic illness with complications involving specific organ systems is rare. During primary maternal infection most (>90%) pregnant women remain asymptomatic.^{226,612} In addition, intrapartum or postnatal transmission from mother to infant during birth or through breast milk is typically silent. Young and premature infants may exhibit hepatomegaly, elevation of liver enzymes, and pneumonitis,^{312,610} although these signs and symptoms have not been observed in studies of term infants.^{170,462,527,617} Asymptomatic infection predominates in all age groups, from preschool-aged children^{6,452} to immunocompetent adults.¹²⁹

Mononucleosis

Clinical signs and symptoms in patients with HCMV mononucleosis are listed in Table 62.5.^{274,299,442} The picture that emerges from these older reports is illness characterized by fever for more than 10 days, malaise, myalgias, headache, and fatigue. Body temperature elevation to 39°C to 40°C is common. Splenomegaly, hepatomegaly, adenopathy, and rash are less common. Several hallmark signs and symptoms of EBV-associated mononucleosis, including pharyngitis, adenopathy, and splenomegaly, are less common with HCMV.

Diagnostic laboratory findings associated with HCMV mononucleosis include lymphocytosis with activated or atypical lymphocytes and elevated hepatic transaminases. Increased

Splenomegaly	33–53
Hepatomegaly	0–53
Rash	0–44
Elevated serum ALT or AST	78–100
Lymphocytosis (>5,000/ μ l)	78–95
Atypical lymphocytes (>1,000/ μ l)	71–95%

Reported patients typically had malaise, fatigue and myalgia as well as features listed in the table.

serum bilirubin and jaundice, signs of hepatitis, are less common. A 1998 review of 116 immunocompetent hospitalized patients with symptomatic HCMV infection reported similar signs and symptoms (compared with Table 62.5), noting sweats in 35 (35%) of 99 and chills in 40 (39%) of 103 of cases. In addition, 20 (17%) of 115 had abdominal pain, 7 (6%) of 112 had diarrhea, and 5 (5%) of 103 experienced 10% or greater weight loss.¹⁸³ A laboratory-based study reviewed clinical findings in 124 immunocompetent adults with serologic evidence of primary HCMV infection (patients whose illnesses had led their general practitioners to test them for HCMV infection)⁷¹⁷ found similar symptoms: 32% of subjects experiencing a constellation of findings that included abnormal liver function tests, malaise, jaundice, sweats, and fever, including 46% with fever, 24% with jaundice, 17% with arthralgia, and 3% with thrombocytopenia. The average duration of symptoms was about 8 weeks (range 1 to 20 weeks) with 12% of patients experiencing relapse. Mononucleosis-like illness can also occur in children. A comparison of adults and children with HCMV mononucleosis found that children were less likely to be febrile (43% versus 94%), but were more likely to have hepatomegaly (100% versus 53%) and splenomegaly (86% versus 53%).⁴⁴²

Severe Infection in the Immunocompetent Host

Rarely, HCMV infection in apparently immunocompetent individuals has been associated with complications involving specific organ systems, and can sometimes even be life-threatening. Reported cases describe a prolonged course of infection that develops into severe illness with multiorgan system involvement.^{171,316} In these rare cases, abnormalities are similar to those encountered in immunocompromised patients, including enteritis, thrombotic disease, hemolytic anemia, thrombocytopenia, encephalitis, neuropathies, myocarditis, and ocular disease, and raises questions about the true immune status of the host. Severe disseminated or focal disease due to HCMV is sufficiently rare that even when suspected, other possible causes should be carefully sought and the immunocompetence of the patient should be assessed.

Because most adults harbor latent HCMV and the virus can actively replicate in critically ill patients for reasons unrelated to illness,¹³⁴ distinguishing HCMV-specific disease can be difficult. Enteritis in association with HCMV infection illustrates this point. A meta-analysis of 41 cases of HCMV colitis reported in immunocompetent individuals between 1980 and 2003 found only 10 cases without comorbidity and 5 cases that were subsequently diagnosed as inflammatory bowel disease.²⁰⁰ Although reports of improvement in following antiviral treatment suggest an etiologic role, a lack of controlled studies, occurrence of spontaneous resolution, and variable outcome of reported cases make it impossible to draw firm conclusions about the relationship of HCMV to enteritis in immunocompetent patients.^{297,533} However, cases are attributed to HCMV when no co-morbidities or evidence of immune impairment are found, and no other potential causes can be identified.

Rare complications in immunocompetent hosts have been linked to primary or ongoing infection, and include venous thromboembolism and pulmonary embolus and recurrent anterior uveitis with iris atrophy.^{3,365} Transverse myelitis, persistent thrombocytopenia, hemolytic anemia, and encephalitis have each been associated with symptomatic HCMV infection in previously healthy persons.^{198,554,683} In a review of HCMV encephalitis in

immunocompetent hosts, evidence of HCMV infection included the detection of virus in the CNS, intrathecal production of antibody to HCMV, or temporal association of symptoms with either a virus culture-positive body fluid or serologic evidence of infection.²⁷ Signs of encephalitis in these patients include confusion, seizures, coma, aphasia, dysphasia, and cranial nerve abnormalities. Deaths during the acute illness have been reported, although encephalitis attributed to HCMV typically resolves spontaneously; however, recovery may take months and leave permanent memory or speech impediment.^{27,638}

Among critically ill intensive care unit patients, active HCMV infection, defined by detection of HCMV DNA in plasma, leukocytes, or tracheal secretions, was unrelated to illness severity.^{134,244} HCMV appeared to cause pneumonia and encephalitis in two patients who died from multiorgan dysfunction. HCMV illness in critically ill patients who are not immunosuppressed is uncommon.

Congenital Infection and Disease

Congenital HCMV infection associated with signs and symptoms of disease, ranging from subtle sensorineural damage such as hearing and eyesight compromise to severe CNS damage and multiorgan involvement, is termed *symptomatic*. A review of 15 relatively large studies (published 1970 to 2004) that screened newborns for HCMV virologically reported that 12.7% of 117,986 newborns with congenital CMV infection were symptomatic at birth.¹⁶² The principal clinical and laboratory findings are shown in Table 62.6, summarizing findings in

TABLE 62.6 Clinical Features of 285 Infants with Symptomatic Congenital CMV Infection Reported to the National Congenital CMV Disease Registry in the U.S. from January 1, 1990 through December 31, 1993

Characteristic	% of infants
Nonneurological abnormalities	
Petechiae or purpura	54
Small for gestational age	47
Hepatosplenomegaly	40
Jaundice at birth	38
Hemolytic anemia	11
Pneumonia	8
Neurologic abnormalities	
One or more of the following	68
Intracranial calcifications	37
Microcephaly	36
Unexplained abnormality	27
Hearing impairment	25
Chorioretinitis	11
Seizures	11
Neonatal death	9
Laboratory abnormalities	
Platelet count $\leq 75,000/\text{mm}^3$	48
Direct bilirubin ≥ 3 mg/dL	36
Alanine aminotransferase level >100 U/L	23

FIGURE 62.5. Computed tomographic scan of the brain of an infant with symptomatic congenital CMV infection demonstrating periventricular calcification.

285 newborns with symptomatic congenital HCMV infection reported to a national registry from 1990 through 1993.²⁶⁵ In an analysis of 106 newborns with disease from Birmingham, AL, two-thirds had clinical evidence of CNS involvement, such as microcephaly, poor feeding, lethargy, generalized hypotonia, or seizures.⁶⁹ Cerebrospinal fluid exhibited elevated protein to greater than 120 mg/dL in approximately 50% of cases. Cranial computed tomographic scans were abnormal in 75% of symptomatic newborns, and periventricular calcification, a hallmark of congenital disease, was the most common abnormality (Fig. 62.5).⁶⁸ Other reported brain abnormalities include cortical atrophy, lissencephaly, and ventriculomegaly. Hearing loss is common in newborns with symptomatic infection; it was present in 56% of tested newborns in the Birmingham study and in 25% in the national registry report, and chorioretinitis was found in 10% and 11% of patients, respectively.^{69,265} Although jaundice, hepatitis, hepatosplenomegaly, petechiae, and thrombocytopenia usually clear spontaneously within a few weeks to a few months following birth, disease in infected newborns can be severe, leading to prolonged hospitalization for supportive care. Neonatal death occurs in approximately 10% of symptomatic newborns. Considering both the frequency and outcome of congenital HCMV infection, it has been estimated to be a leading cause both of sensorineural deafness and of infectious brain damage in children in the United States. Most symptomatic newborns will have some combination of deficits, including mental retardation, cerebral palsy, sensorineural hearing loss, and impaired vision. A literature review estimated a 13.5% rate of CNS sequelae at birth, mainly sensorineural hearing loss.¹⁶² An approximately equal proportion of infants who are asymptomatic at birth have risk may develop CNS sequela over the first months to years of life,⁵³⁵ which has been a motivating factor for universal screening.³¹⁸

The outcome of congenital HCMV infection is influenced by many factors, including gestational age at time of maternal infection, type of maternal infection (primary versus recurrent), specific newborn clinical findings, and viral load in newborn body fluids. Primary maternal infection during the first trimester of pregnancy is more likely to lead to clinical sequelae than infection later during pregnancy. Clinical abnormalities were detected by prenatal ultrasound, autopsy of abortus, or newborn examination in 10 (26%) of 38 congenital cases when primary infection occurred before 20 weeks of gestation, compared with 1 (6.2%) of 16 later in gestation.³³² Newborns with congenital infection exhibited CNS sequelae in 11 (32%) of 34 when primary infection occurred in the first trimester, compared with 6 (15%) of 40 when infection occurred later.⁴⁵⁰ Primary maternal infection has long been associated with more significant CNS sequelae and symptomatic congenital infection than recurrent maternal infection,^{195,612} although severe disease occurs after recurrent maternal infection, leading an impression that maternal infection may not always be predictive of outcome.^{15,66,206} Signs and symptoms of congenital HCMV disease include chorioretinitis (Fig. 62.6), microcephaly, an abnormal neurologic examination, and an abnormal computed tomographic scan of the brain. Congenitally infected newborns shed HCMV in urine and other body fluids at levels, but these levels are not related to risk of disease. In contrast, like other settings of HCMV disease, the level of viremia (typically assessed by quantitative DNA PCR) at birth or early in infancy correlates with congenital disease.^{67,76,317} Comparison of genotype of envelope gN (UL73) from affected and unaffected infants with congenital infection showed a consistent association between gN4 genotype and disease, whereas gN1 and gN3 were associated with less risk of sequelae.⁴⁷⁹ Previous attempts to link outcome to gB or UL144 genotype produced conflicting results. If the gN results can be confirmed, genotyping of strains could provide clinically relevant information and the knowledge of gN genotype associated virulence would likely influence evaluation of candidate vaccines.

Infection in Premature Infants

Among very low birth weight premature infants, acquired HCMV infection is a potential cause of morbidity as shown by studies of transfusion-acquired infection. Exposure to multiple units of blood has been associated with HCMV infection and a clinical syndrome of hepatosplenomegaly, atypical lymphocytosis, thrombocytopenia, worsening of respiratory status, and a septic appearance. Risk for infection was related to very low birth weight and birth to a seronegative mother (correlated with a lack of passively acquired maternal antibody). Transfusion-acquired HCMV infection may be limited by using blood products from seronegative donors or by filtering seropositive blood to remove leukocytes that may transfer virus. Even with current standards that control transfusion-transmitted infections, HCMV infections continue to occur in premature newborns as a result of breastfeeding. Premature infants who acquired virus from a maternal source developed neutropenia, lymphocytosis, thrombocytopenia, hepatosplenomegaly, and worsening of respiratory status.⁷²⁵ Hospitalized very low birth weight premature infants (less than 32 weeks of gestation or less than 1,500 g at birth) in Tübingen, Germany were followed with serial PCR and virus isolation.⁶⁸⁸ Postnatal infection occurred in 59% of premature newborns of seropositive mothers who were breastfed on HCMV-infected milk. Infection was accompanied by symptoms in approximately half of those infected. A sepsis-like syndrome (apnea, bradycardia, gray pallor, bowel distention) was seen in the most severely affected infants who were typically from the lowest birthweight category and had onset of infection within the first 2 months after birth.^{232,234,688} Additional reports identified a similar source of virus, but lower rates or even lack of symptomatic infection.^{387,421,723}

Compared with term infants, premature newborns have lower levels of HCMV-specific IgG, especially when delivered before 28 weeks of gestation. In addition, premature and very low birth weight newborns often rapidly lose maternal IgG because of repeated blood sampling (for supportive care) and transfusion with HCMV-negative blood products. Therefore, the postnatal infection in these infants could be viewed as being similar to congenital infection caused by a primary maternal infection, raising the question of whether small, premature newborns with postnatal HCMV infection might be subject to the same types of sequelae seen in congenital infection.⁴⁴⁵ A number of studies failed to find evidence of neurologic sequelae of postnatal HCMV infection in this population, including sensorineural hearing loss, the most frequent hallmark of congenital HCMV disease.^{272,689} Given the variable study results regarding morbidity of HCMV infection acquired from breastfeeding in small, premature newborns, no consensus exists on what steps should be taken to prevent or treat these infections.⁵⁶³

Opportunistic Infection in the Immunocompromised Host

HCMV is one of the most common, significant, and difficult opportunistic pathogens affecting immunocompromised patients. Infection is common due to reactivation of latent virus, reinfection of patients who have had past infection, and initiation of primary infection through infected tissues and organs. Procedures that are components of patient care (e.g., transfusions or organ transplants) may transmit this virus at a time when the patient is maximally immunosuppressed. HCMV infections in these patients are significant in that severe,

life-threatening disease occurs in a number of settings. Finally, HCMV infections are difficult because diagnosis requires the detection of virus as well as the demonstration that HCMV is associated with disease. HCMV shedding and viremia are common in patients with impaired cellular immunity, even in the absence of disease caused by this virus. The disease risk is proportional to levels of viral markers in the bloodstream, and these roughly parallel the degree to which the patient is immunocompromised.¹⁶⁴ The highest levels of viremia and most consistent severe disease outcomes are seen in recipients of allogeneic HCT as well as in other settings where T-cell immunity is compromised, such as in patients with AIDS with very low CD4 counts. Disease is also seen in SOT recipients, in patients receiving immunosuppressive chemotherapy for cancer or collagen vascular disease, and in congenital immunodeficiencies. Infection may be clinically silent even in the immunocompromised host, and, when it occurs, disease may range from a brief, self-limited febrile illness to multisystem disease with severe consequences.

In addition to the clinical importance of HCMV in the management of immunocompromised patients, infections in various settings have improved understanding of the viral pathogenesis. For example, evidence that reinfection and reactivation can cause disease was first observed in immunocompromised patients. The importance of T cell-mediated immunity in host defense against HCMV, with virus-specific cytotoxic CD8+ T lymphocytes controlling infection, was established in HCT recipients.⁵²⁹ The suggestion that prophylaxis with passive antibody may prevent disease risk was derived from SOT recipients. The first evidence for clinical efficacy of a HCMV vaccine came from studies of live-attenuated Towne vaccine in renal transplant recipients. The development of HCMV-specific antiviral therapies resulted primarily from the need to manage infections in immunocompromised patients, and studies that led to definition of a molecular basis for antiviral resistance were performed in these populations. Finally, the widespread use of automated quantitation of HCMV DNA in blood and body fluids results from the need to manage infection in immunocompromised patients.

Opportunistic Infection Following Solid Organ Transplantation

Managing HCMV infection remains a major problem in transplant recipients and a significant component of the overall cost of an SOT. HCMV disease in this population is most risky when a seronegative recipient is transplanted with a seropositive organ (D+R-) and primary infection occurs in the recipient while receiving immunosuppressive therapy. Studies from the United States, United Kingdom, and France each reported that patients with HCMV disease require more days of hospital care and substantially higher cost of care.^{181,324,375} A 2001 review of the impact of HCMV infection on the cost of solid organ transplantation concluded that HCMV infection in liver transplant recipients was one of the most important variables affecting cost; HCMV disease resulted in approximately \$35,000 increased cost and 18 days longer hospital stay per affected patient during the first year after transplant.⁴⁶¹ A review of hospital readmissions within two years of transplantation among adult renal and heart transplant recipients from five U.S. centers, 1998–1999, found that the average length of stay for care due to HCMV disease was 10 to 11 days at an average cost of \$22,598 for renal transplant recipients and \$42,111 for heart transplant recipients.²⁴⁵

Given the widespread presence of latent virus infection in the population, the potential for HCMV infection must be considered in all solid organ transplant (SOT) recipients. The risk of HCMV disease in this population follows the likelihood of systemic infection: D+R- > D+R+ > D-R+, with D-R- at no risk. Therefore, clinical manifestations of infection in this population can arise from virus acquired with the transplant or from latent virus reactivation within the recipient and may be caused by (a) an acute, systemic, febrile illness (sometimes called *CMV syndrome*), (b) effects on specific organs, or (c) indirect effects.^{188,189,346} Principal signs and symptoms of CMV syndrome include fever and malaise; with occasional arthralgia and rash. Common laboratory manifestations include neutropenia, thrombocytopenia, and elevated hepatic transaminases. Although these nonspecific abnormalities could result from other causes, the presence of HCMV above a certain threshold in blood (usually determined by pp65 antigenemia or PCR detection of DNA as markers of viremia). The role of HCMV in end-organ disease is reinforced by the concurrent onset of abnormalities and rising presence of viral markers in blood. End-organ disease attributed to HCMV on SOT recipients includes pneumonitis, gastrointestinal lesions, hepatitis, retinitis, pancreatitis, myocarditis, and rarely, encephalitis or peripheral neuropathy. Evidence of an etiologic role for HCMV is strengthened by biopsy-proven detection of virus in tissue, assessed histopathologically. Even with current antiviral approaches to prevent severe disease, indirect effects of HCMV infection are seen in this population, including graft rejection, accelerated coronary artery vasculopathy (heart transplant), and increased risk of opportunistic fungal and bacterial infections. Primary HCMV infection in this population has been consistently linked with dysfunction of the transplanted organ, such as renal impairment in kidney recipients, hepatitis after liver transplantation, vasculopathy and chronic graft rejection in heart transplant, and pneumonitis as well as bronchiolitis obliterans following lung or heart-lung transplant. The association between infection (especially primary infection) and increased risk of opportunistic infections, recognized more than 30 years ago, continues to be observed despite available antiviral drugs.^{188,189}

The onset of HCMV infection, as indicated by detection of virus in blood or shedding, is approximately 4 to 8 weeks after SOT, and corresponds to the occurrence of clinical signs and symptoms.¹⁸⁹ The onset of infection and disease is influenced by both the type and level of immunosuppression as well as by the timing of antiviral prophylaxis after transplantation. The sources of infection include reactivation of the latent virus, either within the recipient or from the transplanted organ. Given widespread practice of leukodepletion, blood products are rarely the source of virus, which is why D-R- rarely become infected even when they receive blood from HCMV-seropositive sources. Primary infection acquired by an HCMV-naïve recipient from an organ is recognized as the highest risk setting, although this varies with the specific organ as well as the degree of immunosuppression. Studies performed before the widespread use of prophylactic or preemptive antiviral treatment showed that most patients with primary infection after transplant experienced a febrile illness related to the onset of HCMV excretion, with at least half resolving the infection spontaneously with clinical support. A more recent multicenter study showed that, in the absence of prophylactic antiviral therapy, HCMV disease occurred in 45% of D+/R- renal transplants

and in 6% of patients who were seropositive prior to transplant.³⁵¹ A study of D+/R- liver transplants from a multicenter trial reported that HCMV disease occurred in 17.6% of patients within 12 months of transplant, despite antiviral prophylaxis, up to 100 days after transplant.¹⁹⁷ Although antiviral prophylaxis has proved effective in preventing disease while the antiviral drug is being given, there is a risk of late-onset disease at the time prophylaxis is stopped.^{17,339,506} HCMV disease was reduced to 16% in a randomized, controlled trial comparing 200 days with 100 days of valganciclovir prophylaxis, where most cases were diagnosed as CMV syndrome.²⁵² Alternatively, patients may be monitored for viral markers by quantitative PCR and treated only when viral load exceeds a defined value in whole blood.¹⁶⁴ Such preemptive therapy has a similar efficacy to that of prophylaxis in preventing HCMV end organ disease,^{276,292,517} as recently demonstrated in a large cohort.³⁴

Opportunistic Infection Following Hematopoietic Stem Cell Transplantation

HCMV infection following allogeneic HCT poses the greatest risk when a seropositive recipient receives an allograft from a seronegative donor (D-R+). This setting leaves the transplant recipient without the benefit of immunity, in particular memory CD8+ T cells, while greater histoincompatibility increases graft versus host disease (GvHD), allowing viral reactivation and amplification in the posttransplantation period. Although the incidence of this disease after allogeneic HCT has been dramatically reduced over the last 30 years, antiviral prophylaxis is generally not applied in the immediate posttransplantation period due to concerns that ganciclovir and valganciclovir would delay engraftment. Infection remains a significant problem in this setting because of breakthrough disease in high-risk patients, late onset disease, and indirect effects that adversely affect outcome. Considering that 25 to 30 years ago approximately 25% of at-risk allogeneic HCT recipients developed HCMV disease (usually, pneumonitis) associated with a mortality rate of approximately 85%, remarkable progress has been made. From 1975–1985 to 1992–1994, rates of HCMV disease decreased from 13% to 2.2% and deaths attributed to this virus decreased from 13% to 0% at a transplant center in Sweden.³⁴⁵ Similar results have been reported from a major U.S. transplant center where the incidence of viral disease in allogeneic HCT recipients during the first 100 days posttransplantation dropped from 38% to 5% over an approximate 10-year period.⁵⁹ Reasons for the decline in disease due to this virus include prevention of transfusion-acquired HCMV infection in seronegative patients, decreased frequency of GvHD, use of preemptive antiviral therapy and improved methods for rapid diagnosis and prediction of patients at risk, the availability of effective antiviral agents, and improved understanding of the use of antiviral drugs to prevent disease.

The most common clinical manifestations of HCMV disease in allogeneic HCT recipients are pneumonitis and gastrointestinal disease. Pneumonitis produces an interstitial pattern on radiographs, respiratory distress, and hypoxemia. The diagnosis is supported by clinical signs in temporal association with detection of viral markers in blood, either pp65 antigenemia or quantitative PCR, or by PCR in bronchoalveolar lavage fluid.^{346,665} Gastrointestinal disease usually involves mucosal inflammation or erosion and can occur throughout the tract from esophagus to distal colon. In a review of HCMV

infection and disease in allogeneic HCT recipients in a Swedish hospital, 384 transplants were performed in which donor, recipient, or both were seropositive for HCMV over a 20-year period, and 33 (8.6%) developed HCMV disease.³⁴⁵ Among patients with HCMV disease, 21 (63.6%) had pneumonitis; 3 (9.1%) had pneumonia plus gastrointestinal disease; 6 (18.2%) gastrointestinal disease alone; and there was one case each of hepatitis, encephalitis, and retinitis. The widespread use of preemptive antiviral treatment has reduced the incidence of HCMV disease during the first 3 to 4 months after HCT transplant to approximately 5% or less. In current practice, late-onset disease, usually defined as HCMV disease more than 100 days after transplantation, remains a significant problem in transplant recipients who have had incomplete immune reconstitution.⁶¹

In addition to pneumonitis, gastrointestinal disease, and other clinical abnormalities attributed to this virus, evidence indicates that infection has indirect effects on the outcome in allogeneic HCT recipients just as it does in solid organ transplantation. Although the use of preemptive therapy has benefited the highest risk group for HCMV disease (D–R+), the D+R– setting can experience greater opportunistic bacterial and fungal infections.⁴²⁸ In addition, D+R– HCT experience the most infectious disease complications and highest overall mortality, suggesting a contribution of HCMV reactivation in susceptibility to other pathogens.⁴²⁸ Among patients with myelodysplastic syndromes undergoing HCT, probability of disease-free survival was greater for those who were HCMV seronegative and treatment-related mortality was higher for those who were HCMV seropositive.¹⁰¹ The effect of donor serostatus when donor and recipient are HCMV-seropositive remains controversial.⁶³ In addition to increasing the risk of other opportunistic infections, immunomodulatory effects of HCMV infection enhance GvHD, although mechanisms remain undefined.

In addition to the donor and recipient serostatus, the clinical variables associated with high risk for HCMV disease include donor–recipient histocompatibility mismatch, the conditioning regimen used to ablate the recipient's bone marrow, and the type of immunosuppression used after transplantation.⁶³ HCMV disease risk in HCT is as follows: D–/R+ > D+R+ > D+R–, and is enhanced when the donor and recipient histocompatibility match is less than ideal. Therefore, a matched unrelated donor source is typically more risky than a related donor, and, risk of disease is low following autologous or twin-to-twin HCT. Pretransplantation conditioning regimens that have a greater impact on recipient T cells (e.g., myeloablation) are associated with increased risk for HCMV disease. Similarly, posttransplantation immunosuppression associated with lymphopenia or more severe impairment of T cells (high-dose steroids, mycophenolate mofetil, T-cell depletion, anti-CD52, or anti-thymocyte globulin) result in higher risk of HCMV disease. Graft-versus-host disease is also associated with HCMV disease. Many of these risk factors are interrelated.

Although the approach to diagnosis, prevention, and treatment of HCMV infection varies considerably among stem cell transplant centers, the general consensus is that successful management of HCMV infection requires pretransplant donor and recipient screening, prevention of blood product transmission of HCMV, virologic and clinical screening for HCMV infection and disease posttransplantation, and effective use of antivirals. Because peripheral shedding of HCMV is not predictive of disease in HCT recipients, laboratories have focused

on measuring the quantity of HCMV in blood to determine when antiviral treatment should be given.

Opportunistic Infection in Human Immunodeficiency Virus/Acquired Immunodeficiency Disease Syndrome

Before the use of highly active antiretroviral therapy (HAART), approximately 20% to 40% of adults with AIDS experienced HCMV disease. Among persons with HIV infection, the risk of HCMV disease is linked closely with the loss in cellular associated with a low CD4 T-cell count. Conversely, the use of HAART has resulted in reconstitution or preservation of CD4 T-cell immune function in patients with HIV infection and has dramatically reduced the occurrence of HCMV viremia and disease.⁶²⁴ In the pre-HAART era, the most prominent AIDS-associated HCMV disease was retinitis followed by esophagitis and colitis and less common clinical presentations such as encephalitis, peripheral neuropathy, polyradiculoneuritis, pneumonitis, gastritis, and hepatitis.¹¹⁵ HCMV disease has always been less common in HIV-1–infected children than in adults, a consequence of the lower prevalence of HCMV infection in younger populations. HCMV remains a significant opportunistic infection in patients with HIV infection with significant immune impairment, and guidelines for preventing HCMV disease are focused on patients with fewer than 50 CD4 cells per μL of blood.^{102,103}

Co-infection with HCMV occurs in approximately 90% of HIV-infected women of childbearing age, and women with HIV are more likely to shed HCMV than are HIV-negative women,¹²⁴ probably due to the effect of HIV on immune function. One study in Brazil did not detect a difference in the rates of congenital HCMV infection in newborns of HIV-infected and HIV-negative women⁴²²; however, large cohort studies in the U.S., France, and Spain reported congenital HCMV infection in 2.3% to 4.6% of babies born to HIV-infected mothers, significantly higher than the rate of around 0.7% expected for the general population.^{169,229,364} In addition, decreased rates of HCMV transmission from mother to fetus have been reported in the HAART era compared with pre-HAART data from the same centers.^{229,364} The rate of acquisition of HCMV during birth and early infancy is higher in HIV-infected infants compared to HIV-negative infants.^{229,303,422}

HCMV has been suspected of being a co-factor in the development of AIDS because clinical studies link HCMV and progression of HIV-1 infection, and laboratory studies provide a biologic framework for HCMV enhancement of HIV-1 infection. Although some clinical studies in adults have linked markers of active HCMV infection (e.g., viremia or quantitative plasma HCMV load determined by PCR) with progression of HIV infection, others have not found HCMV to be a risk factor for progression of HIV-1 disease. A study in patients with CD4 counts less than 100/ μL , who were receiving HAART, reported that detection of HCMV DNA in blood by PCR was associated with HCMV disease, a new AIDS-defining condition and death; effects that remained significant in multivariable analyses.¹⁵² During HAART, asymptomatic HCMV infection contributes directly to T-cell activation.²⁵⁵ Among children with HIV-1 studied in the pre-HAART era, HCMV infection was associated with progression to AIDS, encephalopathy, and death.³⁰³ Studies have not been extended to children during the post-HAART era.

Association with Chronic Diseases

In view of the considerable experimental evidence for a key role of vascular endothelial cells in the pathogenesis of HCMV infection and the numerous viral gene products that appear to modulate the host inflammatory response, it is not surprising that this virus has been suspected of playing a role in vascular disease. HCMV contributes to cardiac allograft vasculopathy in heart transplantation⁴⁸⁷ and has been implicated in chronic diseases afflicting the general population, including immune senescence and frailty⁷⁰⁰ as well as cancer,^{128,389,603} although these remain controversial.³²⁵ In addition, the suggestion that HCMV may contribute to autoimmune vascular disorders (systemic sclerosis, polyarteritis nodosa, systemic necrotizing vasculitis, systemic lupus erythematosus, and Sjögren's syndrome). Evidence for a causative role for CMV based on antibody prevalence or serum level of antibody to CMV (or specific viral proteins) is not persuasive; it is difficult to control for the impact of the autoimmune disorder or its treatment on activation of CMV. A report associating antibody to HCMV UL94 with induction of endothelial cell activation, apoptosis, and proliferation of fibroblasts suggests a mechanism through which HCMV could influence the pathogenesis of autoimmune vascular disease.³⁵³

The role of HCMV in atherosclerosis has received considerable attention, but remains controversial. A number of studies link the virus with atherosclerosis, whereas others find no association.⁵³⁴ Studies in elderly women⁷⁰⁰ and Latinos⁵³² reported a greater risk of all-cause mortality and with cardiovascular disease mortality associated with HCMV infection. A large U.S. population-based study showed an association between HCMV seropositivity and all-cause mortality, an association that remained significant in multivariate analyses but did not show any association with cardiovascular disease mortality.⁵⁷⁸ The effect on all-cause mortality was independent of elevated C-reactive protein levels, so further studies may deconvolute the complex relationship between this virus, inflammation, and mortality.

There is growing interest in changes in the relationship with HCMV in aging populations. The elderly, and in particular, frail elderly, have fewer naïve T cells, and more immunocommitted T cells with shorter telomeres, combined with heightened cytokine levels, which has been called “immunosenescence.” Biomarkers of immunosenescence have been found in HCMV-seropositive adults between 42 and 81 years of age but not in an HSV-

seropositive/HCMV seronegative comparison group.¹⁵⁵ The clinical correlates are speculative, but may include excess mortality and impaired immune responses, including to vaccines.⁴⁶⁰

DIAGNOSIS

Differential Diagnosis

When acquired HCMV infection is symptomatic in the normal host, it must be distinguished from other viral and nonviral causes of acute infectious illness characterized by relatively prolonged fever (often, >10 days) and malaise. Other infectious agents that can cause mononucleosis or similar illness (e.g., such as Epstein-Barr Virus, *Toxoplasma gondii*, HIV, and hepatitis viruses A, B, and C) should be considered. Many viral and bacterial infections as well as some autoimmune diseases can cause prolonged fever and malaise, however; when fever persists for more than 14 days, the differential diagnosis is similar to that for fever of unknown origin. Serologic evaluation can be of value in assessing primary HCMV infection.

Congenital HCMV infection cannot be reliably distinguished on clinical grounds from congenital infection caused by other agents such as *Toxoplasma gondii*, syphilis, and rubella virus. Sometimes newborns with postnatal bacterial sepsis have hepatic or splenic enlargement, petechiae, direct hyperbilirubinemia, thrombocytopenia, and neurologic signs similar to those seen in newborns with symptomatic congenital HCMV infection. Newborns with noninfectious diseases such as erythroblastosis fetalis, osteopetrosis, and metabolic diseases can present with jaundice, petechiae, and organomegaly reminiscent of congenital infection. Specific laboratory tests to isolate or detect HCMV resolve the diagnosis in newborns quickly and reliably so long as they are applied within the first 3 weeks of age.

In transplant recipients, many signs of HCMV infection are nonspecific (Table 62.7). A variety of viral (notably, EBV and HHV-6) and other pathogens as well as rejection episodes or GvHD can result in fever, leukopenia, malaise, hepatitis, pneumonitis, enteritis, or impaired graft function. Disease caused by HCMV in patients with AIDS typically presents as retinitis, enteritis, or esophagitis. Although retinitis caused by this virus can be identified with reasonable accuracy by ophthalmologic examination, myriad other possible viral, bacterial,

TABLE 62.7 Common Clinical Effects of HCMV Infection in Immunocompromised Patients

	Solid organ transplantation	Hematopoietic cell transplantation	HIV/AIDS
DIRECT EFFECTS	Acute febrile illness with leukopenia Pneumonitis Esophagitis, gastritis, or enterocolitis Hepatitis Retinitis or other organ involvement	Pneumonitis Esophagitis, gastritis or enterocolitis Less common: encephalitis, retinitis, hepatitis	Retinitis Esophagitis, gastritis, or enterocolitis Peripheral neuropathy, encephalitis Pneumonitis Hepatitis
INDIRECT EFFECTS	Impaired graft function Accelerated coronary stenosis (heart transplant) Opportunistic fungal and bacterial infections Graft failure (controversial)	Opportunistic bacterial and fungal infections Increased mortality (controversial)	Progression to AIDS (controversial)

and fungal causes exist for the other signs and symptoms of HCMV disease in patients with AIDS. Sorting out the role of HCMV infection in immunocompromised patients is facilitated by quantitation of virus in blood by detection of HCMV in affected tissue (lung, eye, CSF, or gastrointestinal mucosa; see *Laboratory Diagnosis* section) and assessment of response to antiviral therapy aimed at HCMV.

Laboratory Diagnosis

Serology

Serologic tests for antibody to HCMV are highly accurate in establishing prior HCMV infection. This assessment is of great clinical importance for organ, HCT, and blood donors, as well as in the pretransplant evaluation of prospective transplant recipients. In addition, serologic tests for seroconversion and for IgM antibody to HCMV are commonly used to establish whether an infection in the immunocompetent host occurred recently. Antibody tests are not useful in the diagnosis of HCMV disease in the immunocompromised host. Although detection of virus-specific IgM antibody has been used to diagnose congenital HCMV infection, direct detection of viral markers is more accurate and is preferred.

Virus Detection

Virus culture detection of HCMV requires inoculation of human embryonic lung or foreskin fibroblast monolayers with clinical material and identification of the slowly developing, focal cytopathic effect (CPE) that is characteristic of HCMV, an approach that is labor intensive and time-consuming. Rapid HCMV isolation in tissue culture based on enhancement of infection of the monolayer by low speed centrifugation and detection of immediate early antigens using monoclonal antibodies allows detection of virus within 24 to 48 hours, and shows similar sensitivity to traditional virus isolation. Real time DNA PCR has become the preferred method for HCMV detection in many clinical virology laboratories because results may be available in a matter of hours, it is more sensitive than culture, and provides a quantification of this viral marker in the sample.

Laboratory Diagnosis of HCMV Infection in Specific Clinical Settings

Primary Infection in the Normal

Host-Maternal Infection

The question of primary maternal infection usually arises as a result of maternal febrile illness, known risk of exposure to HCMV through childcare or sexual activity, or because of a prenatal serologic screening with a positive HCMV-IgM result. The routine testing of pregnant women for antibody to HCMV is controversial; the American College of Obstetricians and Gynecologists and the British Royal College of Obstetricians and Gynecologists state in their respective practice guidelines that screening of pregnant women for HCMV is not recommended and should not be offered as part of routine prenatal care.^{4,507} Primary maternal infection is typically demonstrated by seroconversion from virus-specific IgG negative to positive; however, the initial serum available is often HCMV-IgG positive and other approaches are required. The presence of HCMV-IgM antibody is strongly suggestive of primary infection in symptomatic patients, although antibody assays can vary significantly in sensitivity and specificity and the positive predictive value of a

HCMV-IgM test is likely to be less than 50% when used for prenatal screening. The accuracy of diagnosis of primary maternal HCMV infection has been improved by use of HCMV-IgG antibody avidity assays.^{219,320} Commercial kits for HCMV-IgG antibody avidity determination may vary widely in cut-off values that define low avidity as well as in kinetics of transition from low to high avidity.⁵²² It is important to note that viral shedding in urine, saliva, or genital tract, or even detection of viremia, establishes a primary infection within the preceding 1 to 4 months, which is often the key question when a pregnant woman is first evaluated for possible primary HCMV infection.

Congenital Infection

Congenital HCMV infection is easily diagnosed by the isolation of virus from urine or saliva or detection of viral DNA by PCR within the first 3 weeks after birth. Because HCMV can be transmitted from mother to newborn during birth or in breast milk, virus shedding in newborns first detected after 3 weeks of age cannot be used as an indicator of congenital infection. Congenital infection has been diagnosed retrospectively by PCR detection of HCMV DNA in dried blood spots collected from newborns at birth for metabolic screening. Some investigators report PCR detection of HCMV DNA in blood of all newborns with congenital infection,^{56,327} whereas others report lower rates of viremia using real-time PCR on blood of symptomatic newborns.⁷⁶ A study that screened more than 20,000 newborns reported a low sensitivity of 34% for real-time PCR detection of HCMV in dried blood spots compared with rapid HCMV isolation (detection of early antigen) from saliva,⁷¹ results that argue for refinement of DBS methods to detect congenital infection unless DBS-positive newborns turn out to be more likely to have hearing loss or other sequelae. Results of quantitative DNA PCR in newborns with congenital HCMV infection may have value for prognosis; newborns with higher levels of viral DNA in blood are more likely to have sensorineural hearing loss or other sequelae.^{67,317} There is a nonlinear relationship between viral load and hearing loss, with most damage occurring in those with high viral loads.⁶⁹³ This could explain why short-course ganciclovir therapy in newborns with symptomatic infection protected hearing without an impact on chronic low-level infection.²⁹⁶

In pregnancies complicated by primary maternal infection, the prenatal diagnosis of congenital HCMV infection may be made by detection of virus in amniotic fluid, using virus culture or DNA PCR. Testing amniotic fluid collected at 20 or more weeks of gestation and 6 to 8 weeks from the onset of maternal infection is recommended.³³²

Opportunistic Infection in the Immunocompromised Host

Serologic methods are not useful for identifying HCMV disease episodes in these populations. Viral shedding in urine and saliva is very common in patients with impaired cell-mediated immunity even when they are not experiencing disease. Viral shedding is of limited value except in seronegative populations where shedding can provide evidence of primary infection. The most valuable laboratory diagnostic tests in immunocompromised patients are those that quantitate viral antigens or DNA in blood. In general, higher levels of virus markers in the blood correlate with greater risk of disease. Although commercial quantitative DNA PCR methods for use on whole blood or plasma have been in place at major medical centers,¹⁶⁴ recommendations

regarding threshold quantities of viral DNA that predict disease remain dependent on the clinical setting and other factors. Other approaches are in use—including pp65 antigenemia, quantitative competitive PCR, NASBA for pp67 mRNA and hybrid capture—to complement real-time PCR. Commercial kits are available for some of these, and a number of institutions use in-house assays. Among HCT recipients, lower levels of pp65 antigen–positive cells or of viral DNA in whole blood are predictive of disease than would be considered predictive in solid organ transplantation. Studies that have compared real-time PCR with antigenemia consistently report that more transplant recipients are positive by the former and that infection is detected earlier after transplant with real-time PCR than with the antigenemia assay.^{60,230,326,390} Until a standard approach to quantitation of HCMV in blood is widely accepted, clinicians who manage HCMV infections in immunocompromised patients will need to work closely with their clinical laboratories to determine locally the levels of antigenemia or HCMV DNAemia that are correlated with disease occurrence, recognizing that the threshold levels may vary in different immunocompromised populations.

ANTIVIRAL TREATMENT

The four antiviral agents currently approved by the FDA for treatment of HCMV disease are listed along with dosage information in Table 62.8; their pharmacology is reviewed in Chapter 13. U.S. Food and Drug Administration (FDA)–approved indications for each of these agents are limited to treatment of HCMV infection in immunocompromised patients. Each of these agents has been shown to reduce or eliminate viremia or viral shedding and to prevent or control viral disease in specific settings in immunocompromised patients. Each agent, however, also has the potential for significant toxicity and, therefore, their use is limited to patients who are at risk for serious (disabling or life-threatening) disease. Because HCMV infections in the normal host resolve spontaneously, antiviral treatment is not indicated. Antiviral treatment of

the extremely rare patient with a presumably normal immune system and severe HCMV infection is probably justified if the disease is life-threatening or likely to lead to disability, but will not be discussed further here.¹⁷¹

Treatment and Prevention of HCMV Disease in Patients with HIV Infection

With progressive decline in immune function, active HCMV infection (viral shedding, viremia) is common among HIV/AIDS patients. Before the use of highly active, antiretroviral therapy, HCMV disease accompanied advanced AIDS in adults approximately 40% of the time in the absence of HAART, and a number of clinical trials evaluated antiviral therapy for prevention and treatment of HCMV disease, as reviewed elsewhere.¹⁰² The risk of HCMV disease is closely associated with the level of immune system damage; with a CD4+ T-lymphocyte count of less than 50 cells/ μ L. The ability of HAART antiretroviral therapy to prevent or reverse profound immune impairment in patients with AIDS has resulted in reconstitution of immune responses to HCMV and a dramatic reduction in the frequency of HCMV disease.

Detailed recommendations for preventing and treating HCMV disease in patients with HIV or AIDS have been published and are updated from time to time, and these are posted at the following URL: www.cdc.gov.^{102,103} Consideration of ganciclovir prophylaxis is recommended for HIV-infected adults, adolescents, and children who are HCMV seropositive and who have CD4+ T-lymphocyte counts less than 50 cells/ μ L. Prophylaxis with intravenous ganciclovir is recommended for all patients with HIV or AIDS to prevent recurrences of previous HCMV end-organ disease; valganciclovir orally, cidofovir intravenously, and intravitreal foscarnet are listed as alternatives for adults and adolescents, but not for children. Usual dosages for ganciclovir, valganciclovir, foscarnet, and cidofovir for induction and maintenance therapy are listed in Table 62.8. Discontinuing of prophylaxis for HCMV should be considered for patients with sustained (≥ 6 months) increases in CD4+ T-lymphocyte counts in response to HAART therapy. Ganciclovir or valganciclovir is preferred for antiviral therapy for HCMV

TABLE 62.8 Antiviral Agents Approved for Treatment or Prevention of HCMV Infection in Immunocompromised Adults

Generic (trade name)	More information	Route	Usual adult dose for induction treatment ^a	Maintenance dosage	Major toxicity
Ganciclovir (Cytovene®)	www.rocheusa.com/products/cytovene/pi.pdf	IV oral	5 mg/kg, q12 hour, 14–21 days Not applicable ¹	5 mg/kg/ q24 hour 1,000 mg tid	Hematologic
Valganciclovir (Valcyte®)	www.rocheusa.com/products/valcyte/pi.pdf	oral	900 mg bid, 21 days	900 mg once per day	Hematologic
Foscarnet (foscavir®)	www.rxlist.com/cgi/generic2/foscarnet_cp.htm	IV	90 mg/kg, q12 hr, 14–21 days	90–120 mg/kg once per day	Renal
Cidofovir (Vistide®)	www.gilead.com/pdf/vistide.pdf	IV	5 mg/kg once per week ² , for 2 weeks	5 mg/kg once every 2 weeks	Renal neutropenia

^aRecommended dosages vary considerably depending on renal function, other organ dysfunction, concomitant medications, and indication for treatment; consult the indicated source for prescribing information.

¹Oral ganciclovir is not used for induction treatment.

²Dosage must be individualized based on patient's renal function and probenecid is given prior to dose to minimize renal secretion of drug.

end-organ disease among adults and adolescents with AIDS; cidofovir and foscarnet are listed as alternatives.¹⁰² Following initial induction treatment of 14 to 21 days or until symptomatic improvement has been achieved, chronic maintenance therapy is recommended for patients with HCMV retinitis or neurologic disease but not for patients who have had HCMV pneumonitis, esophagitis, or colitis.¹⁰² Treatment recommendations for children are similar, although there is a lack of data on cidofovir and foscarnet in children mentioned.¹⁰³ For both adults and children, optimized therapy of HIV with antiretroviral drugs remains a very important strategy for prevention and control of HCMV disease in this patient population.

Antiviral Strategies to Prevent Disease in Transplant Recipients

Antiviral agents are commonly used in transplant medicine to prevent HCMV disease, either as a daily prophylactic regimen or in a preemptive approach in which laboratory surveillance for evidence of infection in blood (commonly viral DNA levels by PCR is used as a surrogate for viremia) is used to identify patients at risk of developing HCMV disease who are provided with antiviral therapy until the indicator of infection is eliminated. If the preemptive strategy is employed, monitoring frequency (once or twice weekly or biweekly) and threshold level of viremia at which antiviral treatment is initiated vary according to the type of transplant and other risk factors. An assessment of risk for HCMV disease and potential side effects of antiviral therapy influences the choice of approach. Transplant recipients who are HCMV seronegative and receive a graft from a seronegative donor or an autologous hematopoietic cell graft have little or no risk of HCMV disease, and, assuming transfusion-transmitted infection is avoided, these populations never require preventive antiviral treatment. The highest risk group for HCMV disease in SOT recipients (D+R-) as well as the next highest risk group (D+R+) benefit from prophylaxis or surveillance with preemptive therapy. Additional factors influence approaches to prevention, including type of organ transplanted, donor–recipient histocompatibility, immunosuppressive regimen, and other underlying disease issues.

Consensus panel reports based on critical review of published studies of prophylactic and preemptive approaches to prevention of HCMV disease in SOT recipients provide recommendations based on the available evidence. In general, prophylactic antiviral treatment is recommended for all D+/R- kidney, liver, pancreas, heart, lung, and heart-lung transplants, as well as for all R+ (D-R+ and D+R+) lung and heart-lung transplants and for all patients treated with anti-lymphocyte or antithymocyte globulins or anti-OKT3 monoclonal antibody.^{287,302} Among R+ kidney, liver, pancreas, and heart transplant recipients, either universal prophylaxis or preemptive therapy are considered acceptable approaches; some centers choose to monitor low risk R+ patients and not use a preventive strategy. Antiviral agents used for prevention of HCMV disease in SOT patients include intravenous ganciclovir or oral valganciclovir or valganciclovir; CMV immune globulin is used in some centers. A meta-analysis of studies of prophylactic and preemptive strategies in SOT patients reported no difference between the two in occurrence of HCMV disease.⁵⁹⁰ The choice of preventive approach and duration of preventive medication varies based on specific organ being transplanted, donor and recipient HCMV serostatus, immunosuppressive regimen,

and local custom. Recent reviews should be consulted for details of specific preventive regimens as well as the evidence basis for them.^{174,253,440}

A consensus panel of experts issued guidelines for prevention of opportunistic infections, including HCMV infection in HCT recipients.⁶⁶⁵ The guidelines recommend use of an HCMV disease prevention program for all R+ and all D+/R- HCT recipients from the time of engraftment until 100 days after transplantation. Either prophylactic or preemptive treatment with intravenous ganciclovir was recommended for recipients of allogeneic hematopoietic cells; foscarnet was listed as an alternative antiviral for prophylaxis. If high-dose acyclovir or valganciclovir are used for prophylaxis, virological monitoring is recommended, and treatment with intravenous ganciclovir or foscarnet is recommended if there is virological evidence of HCMV infection. The choice between these two strategies (prophylactic versus preemptive) should be based on an assessment of risks and benefits of each approach, patient factors, and the availability of a clinical laboratory that can provide the rapid turn-around time for quantitation of HCMV in blood that is required for a successful preemptive approach. Virological monitoring should be performed weekly from 10 days to at least 100 days posttransplantation. It was also noted that HCMV-seropositive autologous HCT recipients who have underlying hematologic malignancies or receive specific intense immunosuppressive regimens are at risk for HCMV disease and should be monitored weekly using pp65 antigenemia or quantitative PCR for viremia for the first 60 days after transplantation. Specific recommendations on dose and duration of both prophylactic and preemptive therapy were included in these recommendations.⁶⁶⁵

Although a prophylactic rather than preemptive preventive strategy is usually favored for SOT patients at greatest risk of HCMV disease, this is not necessarily the case for allogeneic HCT recipients. The use of prophylactic antiviral treatment means that all patients are subject to the disadvantages of this approach (notably marrow suppression and delayed engraftment) to prevent HCMV disease that occurs in about one-third of allogeneic HCT recipients without any preventive strategy. Guidelines favor use of the preemptive over the prophylactic approach for D+/R- HCT patients.⁶⁶⁵

Antiviral Treatment for Transplant Patients with Disease

Although preventive strategies have been highly effective in reducing morbidity and mortality from HCMV disease in both SOT and HCT recipients, HCMV disease remains a concern in patients who are either not on a preventive regimen or present with late-onset disease more than 100 days after transplant. In addition, HCMV disease is seen in some patients who were judged to be at low risk and not placed on any preventive program or as breakthrough disease in a small percentage of those on prophylaxis or preemptive regimens. Evidence-based guidelines for treatment of HCMV disease are not available, and no randomized clinical trials have been conducted of antiviral treatment of HCMV disease in transplant recipients. Recommendations for treatment of HCMV have been made in recent reviews.^{174,253} Intravenous ganciclovir or oral valganciclovir are the preferred antiviral agents for treatment, usually given for 2 weeks or until clinical symptoms resolve and viremia falls below a threshold value. Failure to clear viremia has been associated with recurrence of HCMV disease. Maintenance

therapy is used for patients who are at substantial risk for HCMV disease recurrence because of continued immunocompromise; among HCT recipients, maintenance therapy is often continued through the first 100 days after transplantation. Foscarnet is an alternative for treatment of HCMV disease in patients whose virus is resistant to ganciclovir, and in those who fail to respond to ganciclovir, those with marrow failure, or those who cannot tolerate ganciclovir. Recent reviews of antiviral treatment of HCMV disease in SOT and HCT patients provide details of treatment regimens and their effectiveness^{62,174,227,253,347,665}

Antiviral Treatment of Congenital Infection

Antiviral treatment of congenital HCMV infection is currently limited to newborns with signs of congenital HCMV infection at birth. A randomized trial of ganciclovir was limited to newborns that had clear evidence of central nervous system involvement at birth.²⁹⁶ Six weeks of intravenous ganciclovir (6 mg/kg/dose every 12 hours) was compared with no treatment. The proportion of patients with worsening of hearing at 1 or more years of age was 21% in the ganciclovir treated infants, compared with 68% in those who were untreated, $P < 0.01$. In addition follow-up developmental testing of participants showed that a higher proportion of the untreated group failed to attain multiple developmental milestones at the expected ages.⁴³⁷ The American Academy of Pediatrics endorsed treatment of newborns with symptomatic congenital HCMV infection with evidence of CNS damage, but pointed out that whether newborns with less severe disease would benefit from treatment was unknown.¹ Treatment of symptomatic congenital HCMV infection in HIV-exposed or HIV-infected infants with intravenous ganciclovir, 6 mg/kg of body weight every 12 hours for 6 weeks, is recommended.¹⁰³ Newborns with congenital HCMV infection who have no abnormalities at birth should not be treated with intravenous ganciclovir, as the majority of them will have no sequelae of congenital infection and there is currently no means of identifying the approximately 10% to 15% who will subsequently develop hearing loss. Neutropenia was common in newborns treated with ganciclovir and resolved with decreasing dose or suspending treatment.²⁹⁶ Carcinogenicity and reproductive toxicity occur in experimental animals at ganciclovir levels similar to those achieved in treating HCMV infection in humans, another reason to limit ganciclovir in newborns as recommended by the American Academy of Pediatrics. The pharmacokinetics and pharmacodynamics of valganciclovir, a ganciclovir prodrug with good oral bioavailability, suggest it could replace intravenous ganciclovir for treatment of symptomatic congenital HCMV infection. Six months of oral valganciclovir is currently being compared to shorter-course intravenous ganciclovir.⁵⁷⁷

Antiviral Drug Resistance

Chronic administration of antiviral drugs in immunocompromised patients is associated with appearance of mutations in HCMV genes for the UL97 phosphotransferase and UL54 DNA polymerase.¹¹⁸ Specific mutations have been associated with phenotypic resistance to antiviral drugs both *in vitro* and *in vivo* (see Chapter 13 for discussion of the mechanisms and genetics of antiviral drug resistance). Clinically, development of antiviral drug resistance is associated with treatment failure, although it is important to recognize that breakthrough disease or treatment failure occurs in severely immunocompromised

patients with HCMV disease, independent of the appearance of mutations associated with resistance. Genetic mutations associated with resistance are uncommon in patients before antiviral treatment, but are quite common after three or more months of antiviral therapy.²⁶⁷ Patients are often infected with multiple strains of HCMV that may differ with regard to antiviral susceptibility, and resistant strains can persist for months after antiviral therapy has been discontinued.^{119,178} Recognizing and managing antiviral drug resistance in the clinical setting is a complex problem because *in vitro* susceptibility testing is not widely available and the relationship between *in vitro* susceptibility or genotypic changes and clinical effectiveness of ganciclovir, foscarnet, or cidofovir have not been well-defined. The problem is further compounded because one patient isolate selected for evaluation may not accurately reflect the strain or strain mix causing disease. In addition, cross-resistance to cidofovir often occurs in patients with high-level ganciclovir resistance, and patients with multiresistant viruses have been reported.^{119,241}

Clinically significant antiviral drug resistance should be considered a possibility for patients who are responding poorly to treatment. Patients with more significant degrees of immunocompromise, continued HCMV replication while on treatment, or with longer exposure to antiviral therapy are at greater risk for drug resistance. Ganciclovir resistance of HCMV isolates from R+ SOT recipients is rare; among recipients of kidney or pancreas or lung transplants resistance rates range from 1% to 4.4%.³³⁸ Resistance rates are higher among HCMV isolates from D+/R- transplant recipients, ranging from 0 to 5% in kidney, heart, and liver transplant recipients and from 9% to 27% in kidney or pancreas and lung transplant recipients. Among HCT recipients, ganciclovir resistance rates range from 0 to 8.3%.⁶³ If phenotypic or genotypic testing of viral isolates is available, this can be used to guide selection of alternatives, although in practice it may be necessary to make an empiric change in therapy before such results are available. Selecting drugs based on patient isolate susceptibility, optimizing the dose of antiviral medication based on serum levels within the limits of toxicity, and use of combination therapy may all prove beneficial.

PREVENTION OF INFECTION AND DISEASE

Community Acquired Infection

Preventing horizontal transmission of HCMV poses challenges: infected individuals shed virus for months to years; infection in normal hosts is almost always clinically silent and the exposures most likely to transmit HCMV are difficult to avoid. These features of HCMV infection make it difficult to plan strategies for prevention based on limiting exposure to the virus. Exposure to urine and saliva from young children together with adult sexual activity remains the most important sources of virus. However, such exposures are a normal part of life. Two studies provide evidence that the incidence of infection may be reduced in pregnant women by increased hygiene. Women who knew they were seronegative benefited from instruction in techniques for limiting exposure to body fluids, particularly from handling children.^{11,684} The Centers for Disease Control and Prevention (CDC) recommends informing caregivers of infants and young children about HCMV—how it is spread and hygienic measures (e.g., hand-washing) to reduce transmission; in addition, it

is recommended that pregnant women who work with young children should be informed about their risk of HCMV infection as well as the risk of infection to their offspring.^{104,105}

Health Care Workers

Hospital workers do not appear to have an increased risk of HCMV infection, which is consistent with control via infection-control procedures (e.g., handwashing and avoiding contact with body fluids) that are a routine in hospitals and other health care settings. The Hospital Infection Control Practices Advisory Committee of the CDC recommends only standard precautions (the same precautions used to prevent contact with blood and body fluids of all patients) for HCMV and does not recommend screening of hospital workers for HCMV antibody.⁶⁴

Prevention of Infection using Medical Procedures

Blood Transfusion

Transmission of HCMV through blood products to patients who have significant risk of HCMV disease should be avoided. Patient groups at risk for such disease from transfusion include seronegative newborns (especially premature newborns), seronegative pregnant women, patients with AIDS, and organ transplant recipients; however, any patient with impaired cell-mediated immunity may be at risk. Transfusion-transmitted HCMV infections have generally been brought under control by using either leukoreduced or seronegative blood products to prevent exposure of the most at-risk patients. Serologic screening for HCMV and the allocation of blood products according to donor HCMV status adds cost and is of limited value in communities where a high proportion of donors are seropositive. Seronegative blood products have been administered to certain populations (e.g., premature newborns) without prior screening and without a complete understanding of risk, further increasing the demand for seronegative blood products. Given that leukocytes are the main reservoir of HCMV in blood, procedures that remove white blood cells from whole blood by filtration have reduced risk of transmission. Both methods—provision of blood products from seronegative donors and leukoreduction—are effective in preventing transfusion transmitted HCMV, but these two methods may not be equivalent. A study in donor and recipient HCMV-seronegative allogeneic and seronegative autologous HCT recipients ($N = 807$) found a significant difference in the rate of transfusion-transmitted HCMV (1.7%) when only seronegative blood products were used compared to a period when leukoreduction was used (4%),⁴²⁹ and shows that exposure filtered blood from seropositive donors was the key risk factor for HCMV transmission. Similar studies with weekly screening of recipients for HCMV infection and sample sizes sufficiently large to detect low infection rates have not been performed in other at risk populations. Customs vary from institution to institution as to the use of seronegative or filtered blood to prevent HCMV infection, and some differences exist among regulatory authorities and professional associations as to recommendations.⁴⁴¹

Solid Organ Transplantation

The most common source of HCMV infection in organ transplant recipients is reactivation of the transplant recipient's latent virus. Although selection of seronegative donors for seronegative recipients would prevent primary HCMV infection in this

setting, this approach is impractical due to the limited availability of donors. Prophylactic and preemptive antiviral regimens have been used to prevent disease from primary and reactivated HCMV infection as described in the section on antiviral treatment. It is common practice to provide only irradiated, HCMV-seronegative or filtered blood products for transplant recipients. In addition, seronegative transplant recipients and others with profoundly impaired immunity should be cautioned about the risk of HCMV infection through contact with saliva and urine from young children or as well as through sexual contact with adults.

Hospital Cross Infection

Standard precautions are recommended for control of this virus in the hospital.⁶⁴ Human milk is a potential vehicle for nosocomial transmission of HCMV where banking of milk is employed for hospitalized newborns. Milk from seropositive donors should not be given to seronegative newborns, especially those who are premature or hospitalized. A possible exception could be provision of a seropositive mother's milk to her own hospitalized, premature newborn who is seronegative because of prematurity and postnatal decline of passively acquired maternal antibody. Even this situation carries a risk for HCMV disease. Methods for processing milk that reduce HCMV infectivity have been evaluated²³³; a review of HCMV transmission to premature newborns by this route concluded that there was insufficient evidence to support either avoidance or inactivation methods.³¹³

Assisted Reproductive Technology

HCMV has been detected in semen from 2.9% to 33.5% of seropositive donors based on virus culture, DNA hybridization, or PCR.^{53,78,329,362,715} HCMV is transmitted during artificial insemination, resulting in maternal as well as fetal infection. A number of years ago, the American Fertility Society recommended serologic screening of semen donors for antibody to HCMV.¹³ The British Andrology Society has gone further and recommended limiting semen donors to seronegative men with the goal of eliminating the chance of HCMV transmission, a position that elicited dissenting views.^{79,333,383} The American Society for Reproductive Medicine guidelines recommend testing sperm donors for IgG and IgM antibody to HCMV initially and every 6 months, with the donor excluded if the HCMV-IgM antibody test is positive. The serologic tests are repeated before a semen sample is released from quarantine.³³ Donors who are HCMV-IgG and HCMV-IgM negative and those who are positive only for HCMV-IgG (including those who were previously HCMV-IgM positive) are acceptable. Data on HCMV in donated oocytes are very limited; a study of 71 women having infertility evaluations (62% seropositive) reported no detection of HCMV by PCR in any donated oocytes.⁷¹⁵ The American Society for Reproductive Medicine, however, has cautiously recommended the same approach to screening oocyte donors as is recommended for sperm donors.³²

Passive Immunization

CMV-IG is used by some transplant centers in combination with antiviral drugs in SOT patients as part of a prophylactic regimen to reduce HCMV disease. A multicenter, randomized, placebo-controlled clinical trial in D+/R- renal transplant recipients performed more than 25 years ago showed a statistically significant reduction in HCMV disease and opportunistic

fungal and parasitic infections among CMV-IG recipients compared with placebo recipients,⁵⁹⁸ although the rate of HCMV infection was similar in CMV-IG and placebo subgroups. Another multicenter trial performed in liver transplant recipients failed to show efficacy for prevention of HCMV disease in high risk D+/R- recipients, although an overall reduction was seen in severe disease and opportunistic fungal infections.⁵⁹⁷ In the interval since these randomized, placebo-controlled clinical trials of CMV-IG were performed, significant advances in the use of antiviral drugs to prevent HCMV disease in organ transplantation and changes in immunosuppressive regimens have made the role of CMV-IG less clear. A randomized, open-label comparison of CMV-IG with no treatment in HCMV-seropositive lung transplant recipients found no evidence of efficacy for prevention of HCMV disease, viremia, acute rejection, or bronchiolitis obliterans.³⁰⁶ Results of studies of prophylactic regimens comparing combinations of CMV-IG and ganciclovir with single agent therapy differ as to whether the addition of CMV-IG was superior to ganciclovir alone. In an American Society of Transplantation review of diagnosis and management of HCMV infection in SOT patients, there was no recommendation for use of CMV-IG for prevention, but a number of centers employ CMV-IG in conjunction with antiviral agents for prophylaxis of high risk (D+R-) heart, lung or heart-lung transplant recipients.²⁵³

CMV-IG is not recommended for prophylaxis of HCMV infection in HCT⁶⁶⁵ and is no better than IV-IG for reducing GvHD. Passive immunization with donor-derived HCMV specific T cells has been shown to decrease the risk of HCMV disease in allogeneic HCT recipients; however, this approach is difficult to adapt to clinical use.^{127,175,463,464,692}

A randomized, double-blind, placebo-controlled clinical trial evaluated the use of CMV-IG in premature newborns that were transfused with blood from donors not screened for HCMV antibody.⁵⁹⁹ No difference was noted in overall HCMV disease rates between CMV-IG and placebo recipients. Use of blood from seronegative donors or from units that have had white blood cells removed by filtration has been so successful in preventing transfusion-acquired HCMV infection in premature newborns that it has eliminated the need to consider CMV-IG for this indication. Whether CMV-IG could prevent HCMV disease in small, premature newborns infected from a maternal source (intrapartum or milk) is not known.

CMV-IG treatment of pregnant women with primary HCMV infection to prevent fetal infection as well as to treat fetuses with prenatal infection reduced the rate of transmission to the fetus and improved the clinical outcome.⁴³² This study has attracted considerable attention, even though it was not randomized, lacked a control group, study participants self-selected for treatment or no treatment, and investigators who evaluated clinical outcomes were not blinded to treatment used. Although no conclusions regarding efficacy of CMV-IG for preventing transplacental transmission of HCMV infection can be drawn, the possibility of a benefit provided a rationale for further study of CMV-IG for HCMV-infected pregnant women; two randomized, placebo-controlled clinical trials are now addressing this question.^{2,172}

Vaccines

Although an HCMV vaccine has not been licensed, there is a significant body of evidence from clinical trials indicating that

HCMV vaccine candidates can decrease the occurrence of HCMV disease and even prevent infection. Encouraging results were recently reported from clinical trials of a HCMV-subunit glycoprotein B vaccine and from a bivalent plasmid DNA vaccine. More than 20 years ago an efficacy trial in renal transplant recipients using a live virus vaccine (Towne HCMV) showed that pretransplant immunization of seronegative patients with Towne vaccine protected them from severe disease due to primary HCMV infection in the immediate posttransplantation period⁴⁸² as well as protection from a challenge with HCMV strain Toledo,⁴⁸³ although vaccine-induced protection was overcome by a lower dose of challenge virus than the protection afforded by natural infection. Immunization with Towne vaccine did not prevent infection, it did not reactivate, and vaccine virus was never recovered from immunocompromised vaccine recipients. Towne HCMV vaccine was also evaluated in a placebo-controlled trial in seronegative parents of preschool age, HCMV-infected children¹²; however, no evidence of vaccine efficacy was observed and the infection rate remained identical to that of the placebo control group. A subunit vaccine composed of a secreted gB antigen in an oil-in-water emulsion adjuvant (MF59) was evaluated in a phase 2 randomized, placebo-controlled, double-blind clinical trial in young mothers.⁴⁵⁶ The HCMV infection rate was reduced by 50% in vaccinees compared with placebo recipients. Furthermore in a phase 2 randomized, placebo-controlled clinical trial in SOT recipients, HCMVgB/MF59 vaccine was immunogenic and appeared to benefit recipients.²²⁸ Higher antibody titers to gB were associated with shorter duration of viremia; among D+/R- transplants, HCMVgB/MF59 recipients had reduced duration of viremia and reduced need for antiviral treatment compared with placebo recipients. A phase 2 double-blind, placebo-controlled clinical trial of a bivalent (HCMV gB and pp65) plasmid DNA vaccine in HCMV-seropositive HCT patients reported that vaccine recipients had fewer episodes of viremia and were less likely to have repeat episodes compared with placebo recipients.²⁹¹

A number of other vaccines have reached clinical trials evaluating immunogenicity and safety including: vaccines based on a canarypox virus vector,⁴⁹ a chimeric live virus with portions of Towne and Toledo genomes,²⁴³ a modified alphavirus vector (Venezuelan equine encephalitis virus) expressing immunogenic HCMV proteins,⁵¹ and a recombinant HCMV gB antigen with a proprietary adjuvant.⁶³⁹ Additional approaches to vaccine development have been pursued using animal models including subviral particles,⁴⁵ priming with plasmid DNA expressing multiple HCMV genes followed by boost with formalin inactivated virus,⁴⁰⁹ vaccinia vectored gB, pp65 and IE1,⁷³³ replication-deficient adenovirus vectored HCMV antigens,⁷³⁸ and an attenuated HCMV expressing the ligand for an NK-activating receptor.⁵⁸⁶

The relative merits of specific combinations of antigens, adjuvants, and vaccine platforms will be revealed by additional clinical trials. Continued preclinical studies will likely reveal new and possibly superior approaches to any that have been in clinical trials. In addition, there are unanswered questions regarding the optimal target populations for HCMV vaccine clinical trials as well as the prevention of HCMV disease. Although it is unclear when an HCMV vaccine will be licensed, there is continued optimism that vaccines will eventually be able to play a major role in control of HCMV disease.

PERSPECTIVES

As with previous editions of this textbook, we have sought to update the basics of HCMV replication and latency together with a rapidly growing body of information on the interaction with the human host. Our understanding of pathogenesis, immune response, clinical disease settings, and both prophylactic and therapeutic interventions has seen remarkable strides. The breadth of cell intrinsic, innate, and adaptive immune processes that control viral replication is balanced by an armory of virus-encoded modulatory gene products aimed at deflecting those same pathways. It has become clear that HCMV immune modulators that support such a complicated lifestyle, together with those elaborated by other viruses and microbial pathogens, have contributed to the evolutionary adaptation resulting in host defense pathways found in mammals.

In the last few years, a complete sequence of a prototypic HCMV genome has been assembled, and combined with analysis of viral strain variants that arise under different culture conditions as well as during natural replication in patients, an unexpected plasticity has come to light. This plasticity contributes to three broad areas that continue to challenge experimental consensus: (1) seemingly variable behavior of viral strains in cells of a defined cell type, distracting from the goal of mechanistic understanding of key viral properties of persistence, latency and reactivation; (2) common features that engender this virus with a dual capacity for transplacental transmission during pregnancy and opportunistic infection in immunocompromised hosts; and (3) adaptive immune control mechanisms that limit viral transmission as well as disease and would suffice for vaccination to prevent the range of clinically significant infections associated with HCMV. As was true when we prepared the last perspective, we still do not have a definitive picture of the array of cell types that can harbor latent virus, and we certainly do not comprehend the molecular principles that govern latency and reactivation. Despite challenges posed, greater emphasis must be placed on determining whether principles that emerge from cell culture or animal models apply in the natural human host, and these must include observational studies in settings where disease is the outcome as well as clinical trials focused on defined interventions. This virus remains the only human herpesviruses where a subunit-adjuvant vaccine may prevent virus acquisition, which must be pursued. At the same time, no issue remains as glaring as the question of how host immune control is compromised or overcome to allow transplacental transmission during pregnancy.

Bacmid-based molecular genetics and methods for complementation of defective mutants have contributed to a remarkable understanding of HCMV gene function. HCMV studies in cell culture, paired with studies in animal models, have shown the benefit of viral genes that modulate host response to infection, predicting where cell intrinsic, innate NK cell, and adaptive T cell-mediated immune surveillance are most crucial. Endothelial, epithelial, and myeloid cells have begun to yield up requirements for differences in the way viral entry takes place as well as differences in the cellular response to infection manifest by pathogen sensors. The challenge viral strain variants that arise in cultured fibroblasts as well as in all other cultured cell types must be overcome. The macromolecular interactions crucial to viral replication, pathogenesis, latency, and host defense have just started to emerge, and these must to

be extended to natural infection settings where the information will improve clinical management of disease.

Finally, the possible involvement of HCMV in chronic diseases such as vascular disease, immunosenescence, glioblastoma, and salivary gland cancer continues to attract evidence. The path forward is not entirely clear: current antiviral drugs are not always effective in situations where viral etiology is established, and large epidemiological studies needed to develop a definitive correlation are costly and must include settings not confounded by the prevalence of HCMV infection in the population. Immunization might ultimately reduce the universal risk of congenital disease while establishing the contribution this virus makes to any chronic disease.

INTRODUCTION AND HISTORY

Varicella-zoster virus (VZV) belongs to the alphaherpesvirus subfamily of the *Herpesviridae*. Primary VZV infection usually occurs in childhood and causes varicella (chickenpox), characterized by fever and a generalized, pruritic vesicular rash. VZV has tropism for T lymphocytes, which allows dissemination of the virus from mucosal sites of inoculation to skin during primary infection (Fig. 63.1). VZV then becomes latent in ganglionic neurons and may reactivate to cause zoster (shingles), characterized by pain and a dermatomal rash. Declining cell-mediated immunity to VZV, associated with advancing age or immunosuppression, increases the risk of zoster. Zoster may be followed by chronic pain (postherpetic neuralgia) and other neurologic and ocular disorders. Chronic radicular pain and these other disorders also occur in the absence of rash (zoster sine herpete). VZV persists in the human population by transmission to susceptible individuals from contacts with varicella or zoster.

Once thought to be the same disorder, varicella and smallpox were shown to be distinct entities in 1768 by William Herberden. Inflammation of ganglia corresponding to the dermatomal distribution of zoster rash was described by Fredrich Von Baresprung in 1863. In 1900, Head and Campbell mapped the cutaneous dermatomes through an extensive pathologic analysis of ganglionic lesions associated with zoster.²⁵³ In 1892, Von Bokay proposed an infectious etiology for varicella and zoster, postulating that they were related,⁶⁴¹ a concept later supported by the occurrence of varicella in children inoculated with zoster lesion fluid.⁵⁹¹ Garland¹⁸⁵ and Hope-Simpson^{268,269} suggested that zoster was caused by reactivation of latent virus acquired during varicella. In 1953, Weller propagated VZV in tissue culture and found that cytopathic effects, virion morphology, and antigenic profiles were indistinguishable when cells were inoculated with lesion fluid from patients with varicella or zoster.^{672,673} Proof of VZV latency in ganglia came in 1983 from Gilden et al., who showed that radiolabeled VZV DNA probes hybridized to DNA extracted from trigeminal ganglia²⁰⁵ and from Hyman et al., who found

FIGURE 63.1. Model of the pathogenesis of varicella-zoster virus (VZV) infection. Primary VZV infection is acquired by inoculation of mucosal epithelial cells of the upper respiratory tract. Replication at the site of entry allows VZV transfer into tonsils and other local lymphoid tissues, where T cells become infected. Infection of dendritic cells in the mucosal epithelium may support virus transfer to regional lymph nodes. VZV-infected T cells transport the virus to skin sites of replication via a cell-associated viremia. After a 10- to 21-day interval, skin infection produces the vesicular rash associated with varicella (chickenpox). In the course of primary infection, VZ virions gain access to the sensory nerve cell body by retrograde axonal transport or via T cell viremia to establish latent infection within neurons of the sensory ganglia. Episodes of reactivation, during which VZV gains access to skin via anterograde axonal transport, can cause symptoms of zoster (shingles).

that radiolabeled VZV RNA hybridized *in situ* to trigeminal ganglionic neurons.²⁷⁶ In 1984, Straus et al. used restriction endonuclease analysis of VZV DNA from viruses isolated from an immunocompromised patient with varicella and a later episode of zoster to show that reactivation was caused by the original infecting virus.⁶⁰⁷

In 1986, Davison and Scott¹¹⁹ determined the complete nucleotide sequence of the VZV genome (strain Dumas), making VZV the first herpesvirus to be fully sequenced. Since then, sequencing of more than 30 VZV isolates has revealed the remarkable stability of the VZV genome.^{56,407,562} Mutagenesis of the VZV genome using cosmid or bacterial artificial chromosome (BAC) methods has permitted functional analyses of many VZV genes in recombinant viruses.^{100,395,621,715} VZV gene products and promoter elements involved in pathogenesis and modulation of host cellular defenses *in vivo* have been identified by Arvin et al.^{23,24,427,428,707,709} using VZV recombinants containing defined mutations to infect human skin, T cell, and dorsal root ganglia xenografts in a SCID mouse model.^{23,24,427,428,707,709} Major clinical advances were achieved with the development of the live attenuated varicella vaccine from the Oka strain by Takahashi in 1974, making varicella^{610,611} and zoster⁴⁸² the only vaccine-preventable human herpesvirus infections and the

identification of antiviral agents effective against varicella and zoster in the 1980s.^{36,142,677,678}

CLASSIFICATION

The genus *Varicellovirus* of the alphaherpesvirus subfamily includes VZV, simian varicella virus (SVV) (cercopithecine herpesvirus 9), pseudorabiesvirus (PRV) (suid herpesvirus 1), and equine herpesvirus 1 (equid herpesvirus 1). VZV is most closely related to SVV.^{215,216,217} These viruses disseminate through their natural hosts to infect the skin, mucous membranes, and visceral and nervous system tissues. They also share a genomic arrangement in which isomeric forms are generated by inversion of the shorter unique DNA segment and its flanking repeat elements. VZV is the species name of the only varicellovirus known to infect humans. The three human alphaherpesviruses are VZV, which has a very narrow host range restricted almost exclusively to cells of human or simian origin, and the herpes simplex viruses HSV-1 and HSV-2, which replicate in cells and tissues of many mammalian species. All three viruses become latent in ganglia along the entire neuraxis, from which they can reactivate to cause recurrent viral shedding or disease.

Varicella-zoster virus infections: biology, natural history, treatment, and prevention. *Ann Intern Med* 1988;108:221–237. **E–G** courtesy of M. Reichelt, X. Che and A. Arvin).

VIRION STRUCTURE

Morphology

The VZ virion structure has not been investigated completely, in part because cell-free progeny virions cannot be produced efficiently from cultured cells. Nonetheless, the four major components of VZV particles, like those of the other herpesviruses, are the core, nucleocapsid, tegument, and envelope (Fig. 63.2).

The Core

One copy of the linear, double-stranded DNA (dsDNA) VZV genome is presumed to be incorporated into each virion. Particles fixed with nondehydrating agents and imaged by electron microscopy (EM) reveal a loose fibrillar cage of strands surrounding a dense cylindrical core of DNA fibers.⁵¹² The packaging of the HSV genome in regularly spaced layers within the nucleocapsid may be relevant to VZV structure.

The Nucleocapsid

The VZV nucleocapsid is indistinguishable from those of other herpesviruses. It consists of 162 capsomere proteins with a 5:3:2 axial symmetry, in which pentameric proteins form the vertices of an 80-nm to 120-nm icosahedron, while hexameric elements comprise its facets. VZV nucleocapsids recovered from cell culture often lack dense cores associated with genome

packaging, consistent with the low infectivity of VZV particles produced *in vitro*.²⁴⁵ The VZV gene products that comprise the assembled nucleocapsid have not all been verified, but are expected to include the products of VZV open reading frames (ORFs) 20, 21, 23, 33, 40, and 41, by analogy with their herpesvirus homologs.

The Tegument and the Envelope

The VZV tegument includes three immediate early (IE) proteins encoded by ORFs 4, 62, and 63.^{321,324} In addition, the ORF9 to ORF12 gene cluster, conserved in alphaherpesviruses, encodes three tegument proteins, ORF9 to ORF11, and the putative tegument protein, ORF12.⁷⁶ The viral kinases, encoded by ORF47 and ORF66, are also tegument proteins.⁵⁹⁶ ORFs 22, 38, 53, 57 and 64/69 are putative tegument proteins.⁷¹⁵ Tegument proteins are acquired by the nucleocapsid, which is then enveloped within patches of host cellular membranes that have been modified to display virally encoded glycoproteins. The particle is further modified as it is transported along membranous networks that extend from the nuclear membrane to the cell surface. Virions accumulate at the plasma membrane, transit across this membrane and infect cells in close proximity. Since particles can capture membranous elements of the endoplasmic reticulum (ER), cytoplasmic vesicles, and the cell surface, the VZV envelope does not appear to have a single source.¹¹³ The mature VZV particle, consisting

of the nucleocapsid, tegument, and lipid membrane envelope, is pleomorphic-to-spherical and 180 to 200 nm in diameter.

Physical and Chemical Properties

The VZV lipid-rich envelope renders it susceptible to degradation and loss of infectivity by brief treatments with organic solvents, detergents or proteases, heating to 60°C, prolonged storage at temperatures of -70°C or above, extremes of pH, or ultrasonic disruption.^{69,141,210} In cesium chloride gradients, enveloped VZV particles band at a buoyant density of 1.274 g/cm³ while VZV DNA exhibits a buoyant density in cesium chloride of 1.705 g/cm³.

GENOMIC STRUCTURE AND ORGANIZATION

The dsDNA genomes of the alphaherpesviruses range in size from 124,784 to 164,270 base pairs (bp); VZV and SVV are the smallest at ~125,000 bp.^{91,217} The VZV genome consists of a unique long region (UL) of about 105,000 bp flanked by inverted repeat regions, the terminal repeat long (TRL) and internal repeat long (IRL) sequences, each 88.5 bp, and a unique short region (US) of 5,232 bp that is flanked by internal repeat regions, the terminal repeat short (TRS) and inverted repeat short (IRS), each 7,319.5 bp (Fig. 63.3). Overall, 46% of VZV bases are G + C, whereas the G + C content of its repeat elements is 59% for the TRS and IRS regions and 68% for the TRL and IRL regions. Unlike SVV and other varicelloviruses, VZV lacks a terminal region with flanking inverted repeats at the left end of the genome.²¹⁷

VZ virions usually contain the VZV genome as a linear molecule; a circular, supercoiled conformation is detected as a rare alternate structure.^{327,603} The genome has four potential isoforms but two predominate,^{148,603} with 50% of VZV genomes extracted from nucleocapsids showing the US directed in a single orientation and 95% showing a single orientation of

the UL region.^{117,327} The linear VZV genome has an unpaired cytosine at its left end and a guanine at the right end, which can pair to form a circular molecule.¹¹⁷ In latency, the termini are covalently joined, circularizing the genome.⁸⁸

ORFS/L (or ORF 0), located at the end of the UL segment, encodes a protein essential for replication.^{302,308,714} However, mutagenesis of the extreme 5' terminus of ORFS/L also results in defective DNA cleavage.³⁰² This UL sequence is not duplicated at the opposite end of the UL, which may explain why UL is found in a single orientation in 95% of genomic DNA extracted from nucleocapsids.

The VZV genome encodes at least 70 ORFs, three of which are present in two copies in the IRS and TRS regions (Fig. 63.3; Table 63.1). Mutagenesis studies indicate that about 44 ORFs are essential for replication *in vitro*, with some variations depending on experimental conditions. Twelve of 26 genes dispensable for replication in cell culture are in the genome region from *ORFS/L* to *15*.^{91,715} Gene duplication in the IRS and TRS regions is highly preserved since removal of one copy of the gene pairs *ORF62/71*, *ORF63/70* or *ORF64/69* is corrected after a few replication cycles.^{472,580} Many VZV ORFs are arranged in unidirectional groups of up to four genes with a single putative polyadenylation signal at the 3' end of the group. Eleven VZV ORFs have overlapping coding sequences. *ORFs 42* and *45* are thought to be spliced segments of the same gene.¹¹⁹ *ORFS/L* is spliced in the 3' noncoding region³⁰⁸ in VZV strains including parent OKA, but it is not spliced in vaccine Oka and produces two protein products.³³⁷

The VZV genome has five small regions, R1 through R5, which vary in length and contain different numbers of identically oriented short sequence repeats; VZV has relatively few repeats compared to PRV and HSV-1.¹⁵⁶ These repeat regions result in distinct electrophoretic profiles by restriction enzyme analysis.^{119,604} The R1, R2, and R3 regions are GC rich and located in the UL segment of the genome. The R1 region, located within *ORF11*, consists of four separate repeats of 15 or

FIGURE 63.3. Organization of the varicella-zoster virus (VZV) genome and known or predicted open reading frames encoding viral proteins. The VZV genome has unique long (UL) and unique short (US) regions flanked by internal repeat (IR) and terminal repeat (TR) regions. VZV has 40 core genes that are conserved among α -, β - and γ -herpesviruses; these gene products participate in DNA replication (blue), DNA cleavage and packaging (green), nucleic acid metabolism (yellow), capsid protein assembly (red), or are envelope glycoproteins (orange) or have other functions (pink). The genes that are not conserved among the other herpesviruses may be nonessential for VZV replication in cultured cells (white), or may be essential (gray), three of which are envelope glycoproteins (black). Six VZV genes have no HSV-1 homolog (*). Open arrows and dark arrows indicate repeats (R1–R5) and the origins of DNA replication (*ori*), respectively. When the genome is circularized, ORF S/L (ORF 0) begins at the right end and extends across the terminal repeat into the UL region at the left end.

NL: normal as compared to wild type VZV.

^aIndicates predicted function based on conserved sequence.^bDefined by mutagenesis of the VZV genome (pOka or vaccine Oka) using cosmids or BACs to delete, insert stop codon, or introduce targeted changes in the coding sequence.^cIndicates differences among published observations about whether the gene is essential or dispensable, including variations in mutations tested and/or experimental conditions used to assess growth requirement.

FIGURE 63.4. Phylogenetic tree of varicella-zoster virus (VZV) genogroups and their nomenclatures. Clades 1, 3, and 5 include isolates of European origin; clade 2 has Asian isolates, including the parent Oka virus used to derive VZV vaccines, and clade 4 has isolates from tropical Africa. (Adapted from Breuer J. VZV molecular epidemiology. *Curr Top Microbiol Immunol* 2010;342:15–42).

18 bp. The R2 region is located within *ORF14*, which encodes glycoprotein C (gC), and consists of 42-bp repeats in multiples that differ among VZV isolates.³²⁸ The largest repeat region, R3, is about 1,000 bp in length and located in *ORF22*.¹¹⁹ The GC-rich R4 region is located in both IRS and TRS regions between *ORF62* and *ORF63* (and *ORF70* and *ORF71*), consisting of multiple 27-bp elements.⁶⁸ The A-T rich R5 region, located between *ORF60* and *ORF61*, consists of both 88-bp and 24-bp repeats.¹⁹⁷ The Dumas strain of VZV has only one copy of the R5 repeat, while other strains of VZV have multiple R5 repeats.

Full-length genomic sequencing of more than 30 VZV isolates has revealed that the VZV genome is very stable and exhibits little geographic diversity.^{56,251,451,562} The few consistent differences among geographically distinct VZV isolates allow their classification into five distinct phylogenetic clades (Fig. 63.4). Clades 1 and 2 are the most divergent but are still 99.83% identical. The parent clinical isolate used to derive the vaccine Oka stock virus is clade 2. Comparison of the sequence of the Oka vaccine virus with that of the parent Oka virus revealed 63 sites that differ.¹⁰⁹ The nucleotide sequence could not be unambiguously determined in 27 sites because the Oka vaccine stock is a mixture of genomes with nucleotide polymorphisms.^{211,298a} Of interest, 15 of the 42 nucleotide differences in Oka vaccine are in *ORF62* and account for 8 of the 20 predicted amino acid changes. VZV has been calculated to undergo about 20 replicative cycles in the human host before latency is established, suggesting limited opportunity for the accumulation of genetic mutations.²²³ Mutations in the VZV genome were also minimal after more than 1,200 serial passages in tissue culture.²⁴⁶

Comparison of the VZV genome with those of the seven other human herpesviruses indicates that VZV shares at least 40 conserved genes, all of which are among the 62 genes located in the UL region. These conserved genes encode an IE protein (*ORF4*); the DNA polymerase; helicase-primase complex proteins; other viral enzymes; the *ORF47* kinase and structural proteins, including the major nucleocapsid and related proteins for assembly; and the glycoproteins gB, gH, gL, gM, and gN.

Large portions of the VZV genome are co-linear with the HSV-1 genome, and the predicted amino acid sequences of many VZV and HSV-1 gene products have identical or similar regions (Table 63.1). Of the 62 genes in the VZV UL region, 56 have HSV homologs, as do all four of the genes encoded in the VZV US region.⁹⁰ Nevertheless, while functions may be conserved even with limited sequence similarities,¹⁷² predictions must be confirmed empirically, as illustrated by differences in the roles of VZV *ORF61* and HSV-1 *ICP0*,⁶⁵⁴ and of *ORF10* and HSV-1 *VP16* (UL48).⁷⁷

Six VZV ORFs (*ORFs 1, 2, 13, 32, 57, and S/L*) have no HSV-1 homologs and each is dispensable for VZV replication in cell culture.^{100,103,114,308,338,521,553} *ORFs 1, 32, and 57* have homologs in SVV and the equine herpesviruses.²¹⁷ *ORF13* has no related gene in the other alphaherpesviruses, but has a homolog in a gammaherpesvirus, the human herpesvirus 8.

STAGES OF REPLICATION

Overall Pattern of Replication

As with other herpesviruses, VZV is presumed to attach to cells by fusion of the viral envelope with the cytoplasmic membrane

FIGURE 63.5. Replication of varicella-zoster virus (VZV). The schema shown accommodates observations from multiple sources and relies on analogies drawn from studies of herpes simplex virus (HSV) replication. VZV may enter cells by attaching to cell-surface glycosaminoglycans followed by binding to receptor(s) (*R*) on the plasma membrane (1a), or by endocytosis followed by interaction with a receptor(s) in the endosome (1b). The nucleocapsids penetrate the cell (2) and enter the nucleus where, with the aid of regulatory tegument proteins encoded by IE4, ORF10, and IE62, a cascade of viral immediate-early (*IE*), early (*E*), and late (*L*) transcripts and proteins is synthesized (3). Viral DNA replication follows a rolling-circle model (4). Nucleocapsids are assembled and package newly synthesized DNA (5). Nucleocapsids appear to be transiently enveloped as they bud through the inner nuclear lamellae (6). These nucleocapsids lose their envelopes upon fusion with the rough endoplasmic reticulum, resulting in the release of naked nucleocapsids into the cytoplasm (7). Virion glycoproteins are synthesized in the rough endoplasmic reticulum, mature in the Golgi apparatus, and line the inner surfaces of cytoplasmic vesicles. Viral tegument proteins are synthesized by free ribosomes and line the outer surfaces of the cytoplasmic vesicles. Nascent particles are drawn into these vesicles, where intact, enveloped virions coalesce (8).¹⁹³ These vacuoles may fuse with the cell membrane to release infectious progeny (9), although some fuse with prelysosomes in which the particle is partially degraded before release. Alternatively, nucleocapsids may retain their envelopes as they egress the nucleus (10).²⁴⁵ Their envelopes are glycosylated by fusion with Golgi-derived vesicles. Late in infection, some particles may reenter the nucleus (11), although most are transported to the cell surface for release (12) or to prelysosomes (13).

followed by endocytosis (Fig. 63.5). On entry, VZV tegument proteins encoded by *ORFs* 4, 10, and 62^{321,324} are likely transported with the nucleocapsid to the nucleus, where they may initiate viral gene transcription. ORF61 is expressed along with IE62 shortly after virus entry⁵²⁵ but is not a tegument protein. Other tegument proteins, including IE63 and the viral kinases ORF 47 and 66, are also likely to be important early in infection. VZV IE messenger RNAs (mRNAs) are transcribed, transported to the cytoplasm and translated, and the encoded proteins are transported back to the nucleus. VZV early mRNAs may then be transcribed, translated, and shuttled to the nucleus to facilitate viral DNA replication. Replication compartments containing IE62, the single-stranded DNA (ssDNA) binding protein, ORF29, and nascent VZV DNA

are formed within 4 hours after infection.⁵²⁵ Thereafter, VZV late mRNAs are transcribed and translated and the proteins enter the nucleus for assembly into nascent capsids. Newly replicated VZV DNA is packaged into capsids that egress from the nucleus and are enveloped in the cytoplasm. The life cycle from entry to formation of mature enveloped VZ virions is completed in about 9 hours *in vitro*. By 12 hours, enveloped viruses are abundant in the cytoplasm and extracellularly along plasma membranes. The externalized enveloped virus particles are presumed to bind surface receptors, fuse with membranes of adjacent cells and begin synthesis of progeny virions. While syncytia formation is a hallmark of VZV infection, cell–cell fusion is not required to initiate the infectious process; however, the uninfected cell must be in close proximity to an

infected cell, suggesting that virions attached to cell surfaces are transferred into neighboring cells.⁵²⁵

The basic events in VZV replication have been defined in cell culture using intact virus and VZV recombinants with targeted mutations in viral genes and promoter regions to map protein and promoter functions (Table 63.1). However, many important characteristics of the regulation of gene expression and the essential or important functions of viral gene products during the viral life cycle are not identifiable *in vitro*, but are evident when specialized human cells are infected *in vitro* or in their tissue microenvironments in human xenografts in the SCID mouse model *in vivo* (Table 63.1).

Attachment, Entry, and Uncoating

The initial attachment of alphaherpesvirus particles to the cell surface appears to entail nonspecific electrostatic interactions between viral envelope glycoproteins and cellular surface glycosaminoglycans such as heparan sulfate. In HSV, glycoproteins B and C (gB, gC) participate in electrostatic attachment to cells. VZV gB binds to heparan sulfate,²⁸⁸ but it is uncertain whether gC does so. Whereas HSV gD and its homologs in other alphaherpesviruses bind to cell surface receptor molecules known as herpesvirus entry mediators, VZV lacks a gD homolog and may not use any of these receptors. The cation-independent mannose 6-phosphate receptor may facilitate VZV entry by interacting with viral glycoproteins that contain phosphorylated N-linked complex oligosaccharides.^{82,716}

After attachment, studies of other herpesviruses indicate that the highly conserved glycoproteins gB, gH, and gL are required for fusion of the viral envelope with the cell membrane. The VZV gB structure, including the putative fusion loops, is similar to that of HSV-1 gB by homology modeling, and gB residues in the primary loop are essential for VZV replication.⁴⁷³ VZV gH appears to facilitate fusion of the VZV envelope with the cell membrane since antibodies to gH block VZV entry in cultured cells; however, anti-gH antibody is also internalized by infected cells,⁶³⁹ inhibiting syncytia formation and virion egress.⁵³⁴ The gH C-terminus has a loop structure essential for gB/gH/gL-mediated fusion.⁶⁴⁰ The extreme N-terminus of VZV gH is important for replication *in vitro* and in skin and may interact with a cell-surface protein since this region of gH in other herpesviruses interacts with $\alpha\beta$ integrins.⁶⁴⁰ Interactions of gB with the myelin-associated glycoprotein (MAG) contributes to cell–cell fusion mediated by gB and gH/gL in neural cells.⁶⁰⁹ VZV gE is an abundant glycoprotein that forms heterodimers with gI and binds to insulin-degrading enzyme (IDE) in VZV-infected cells.³⁶⁴ Inhibition of IDE reduces VZV infectivity while IDE expression enhances infection of nonhuman cell lines, suggesting a contribution to entry. However, IDE binds to immature gE in the cytoplasm, which is not a receptor–ligand interaction,⁶⁶ and gE mutants with disrupted IDE binding can infect cells in culture and are not impaired in their ability to enter T cells *in vitro* or *in vivo*.⁴²

Once virus entry has occurred, herpesvirus nucleocapsids are transported to the nuclear membrane and the viral genome is delivered into the nucleus. Neither the role of specific viral proteins and cellular cytoskeletal elements in facilitating the centripetal movement of VZ virions to the nucleus nor the composition of the virion reaching the nuclear membrane has been determined.

Transcription and Translation

The transcription and translation of VZV genes in infected cells depends on viral transactivating proteins that act in conjunction with host-cell RNA polymerase II and the cellular transcription and translation machinery. VZV proteins with transactivating capacity are encoded by *ORFs* 4, 10, 61, 62, and 63; IE62 is the predominant viral transcription factor. While VZV gene transcription is likely to follow a coordinated temporal program analogous to that of HSV, the transcriptional cascade has remained undefined because synchronous infection cannot be established with low titers of cell-free VZV recoverable from cultured cells. However, the kinetics of expression of six representative VZV proteins, ORF61, IE62, IE63, ORF29 (ssDNA binding protein), ORF23 (small capsid protein) and gE was established using markers differentiating inoculum from newly infected cells⁵²⁵ (Fig. 63.6). IE62 and ORF61 are synthesized first (within 1 hour); IE63 is expressed at 4 hours. The localization of IE62 to small nuclear punctae is a marker of the earliest stage of replication. Infection in the presence of cycloheximide followed by actinomycin-D indicates that VZV *ORF4*,¹²² as well as *ORF62* and *ORF63*,¹²⁰ encode IE proteins. Although each of the HSV-1 homologs of *ORF* 4, 62, and 63 contains an upstream TAATGARAT sequence element, only the VZV *ORF62* promoter region has TAATGARAT-like promoter elements.^{329,437}

Transcriptional arrays of VZV-infected monkey kidney cells show that *ORFs* 9, 33, 49, 57, 63, and 64 are the most abundant viral transcripts,¹⁰⁷ whereas arrays from virus-infected melanoma cells showed highest expression of *ORFs* 9, 48, 49, 57, 58, and 64.³¹² Transcripts not known to encode proteins are detected from sequences between *ORFs* 60 and 61, 61 and 62, and 62 and 63.¹⁰⁷ VZV transcription mapping revealed 78 abundant transcripts of 6.8 kb or smaller,³⁹⁵ many of which were located in regions corresponding to the *ORFs* predicted by Davison and Scott,¹¹⁹ but most could not be assigned with certainty to a given gene.

As is observed in other herpesviruses, multiple co-linear and co-terminal transcripts can encode a single VZV protein. VZV uses TATA elements and polyadenylation signals whose sequences may differ from consensus sequences.^{119,370} VZV, like HSV-1, contains GU-rich sequences GTCTGTGT and TGGTGGTA downstream of polyadenylation sites that may be important for termination of transcription.³⁷⁰ VZV genes homologous to HSV-1 genes may have different patterns of transcription. For example, *ORF14* (gC)³⁷⁰ and *ORF61*⁵⁹⁵ appear to be expressed from unspliced transcripts, in contrast to their HSV-1 homologs. Different strains of VZV may also vary in the level of transcription of a given gene. For example, VZV strain Scott expresses about 20 times more gC mRNA than does VZV strain Oka.³⁷⁰ Another feature of VZV transcription is the regulation of VZV polymerase (*ORF28*) and the major DNA binding protein (*ORF29*) by a single bidirectional promoter with shared promoter elements. Both this *ORF28–29* bidirectional promoter^{411,412,519,541} and the *ORF4* promoter are activated by the interaction of IE62 with the transcription factor upstream stimulatory factor (USF). A binding site for the nuclear regulatory protein Sp1 modulates the activity of both of these promoters, whereas one TATA box controls expression from the *ORF28* promoter and two other TATA elements regulate expression from the *ORF29* promoter.⁶⁹⁵ Transcription of *ORFs* 62 and 63 is also mediated from a bidirectional promoter.²⁹⁵

FIGURE 63.6. The spatio-temporal pattern of expression of selected varicella-zoster virus (VZV) immediate-early, early, and late proteins and viral genomic DNA. Cells were fixed and imaged at 0 (not shown), 2, 4, 6, 9, and 12 hours after inoculation of unlabeled human fibroblasts with input cells labeled with green CellTracker. Cells were then stained with specific antibodies for VZV proteins ORF61, IE62, IE63, ORF29, gE, and ORF23 (from left to right) followed by Texas red-conjugated secondary antibodies to detect proteins (red). VZV DNA was detected by *in situ* hybridization (red). Cell nuclei were counterstained with Hoechst 22358. Ten fields of 30 to 50 output cells were scanned to determine the representative staining patterns in newly infected cells at each time point. Single representative cells or nuclei are shown. PM, plasma membrane; cytoplasm, cytoplasm. (From Reichelt M, Brady J, Arvin AM. The replication cycle of varicella-zoster virus: analysis of the kinetics of viral protein expression, genome synthesis, and virion assembly at the single-cell level. *J Virol* 2009;83(8):3904–3918, with permission.)

VZV Proteins that Regulate Viral Gene Transcription

Five VZV proteins, encoded by *ORFs* 4, 10, 61, 62, and 63, can regulate viral gene expression. Most promoters of VZV genes also have binding motifs for cellular transcription factors, such as Sp1, USF and activating transcription factor (ATF), that contribute to viral gene expression. These cellular transactivators can be critical for VZV replication *in vitro* and in human skin and T cell xenografts *in vivo*.⁵⁴¹ All of these proteins except ORF61 are known tegument components.³²¹ ORF61 and IE62 also have important functions in counteracting intrinsic antiviral cellular responses (see Effects on the Host Cell).

IE62

ORF62 (at least one copy) is essential for VZV replication.⁵⁴⁹ This gene encodes IE62, a 1310-amino acid protein,^{167,324} which is the most potent and promiscuous viral transactivat-

ing factor. IE62 has an acidic transcriptional activation domain and a DNA binding domain. IE62 binds directly to the cellular transcription factors Sp1 and USF and to the cellular TATA binding protein and general transcription factor (TFIIB).⁵⁴¹ IE62 binding to the viral proteins IE4 and IE63 modulates its transactivating functions. IE62 has a nuclear localization signal³⁹ and is localized primarily in the nuclei of infected cells, with some cytoplasmic expression at later stages of infection (Fig. 63.6). IE62 is phosphorylated and requires the kinase activity of ORF47 protein for cytoplasmic versus nuclear localization.⁴⁵ Co-expression of the ORF66 kinase with IE62 results in cytoplasmic accumulation of IE62³²³ (although not in T cells),⁵⁶⁰ and ORF66 is required for IE62 incorporation into virions in cultured cells.³²²

A single amino acid change in the DNA binding domain of IE62 results in loss of its transactivating function.⁶²³ IE62 is the homolog of HSV-1 infected cell protein (ICP)4 and can complement ICP4 mutants.^{135,167} However, the DNA binding

domain of IE62 is less sequence specific and, unlike ICP4, does not induce DNA bending on binding its own promoter.⁶²⁴ The transcriptional activation domain (TAD) at the IE62 amino terminus is not conserved in HSV-1 ICP4 or HSV-1 viral protein (VP)16.^{93,496,541} This IE62 TAD interacts with the mammalian Mediator complex involved in RNA polymerase II-mediated transcription,⁶⁹⁶ an interaction that appears to be required for IE62 TAD-mediated activation, specifically through the MED25 subunit (eFig. 63.1).

IE62 transactivates expression of putative IE (*ORF4*, *ORF61*), early, and late gene promoters in transient expression assays^{278,495} and activates its own promoter in a lymphocyte-derived cell line but not in simian cells.^{136,167,497} The differential activation of promoters by IE62 reflects its capacity to interact with cellular transcription factors and depends on the sequence of the TATA motif in the targeted promoter.⁴⁹³ IE62 also increases the infectivity of transfected VZV DNA.⁴⁴⁵

Recruitment of IE62 is enhanced by the presence of an Sp1 site within the gI promoter.⁴⁹² Interaction with Sp1 and possibly other Sp1 family members appears to be an important aspect of IE62 activation. Several other Sp1 sites within VZV promoters have been validated as important for IE62-mediated activation, including the essential proteins gE⁴⁰ and ORF61.⁶⁵³ Bioinformatics analysis of the VZV genome has identified Sp1 sites within almost all predicted promoter elements.⁵⁴¹

The mechanism of activation of the *ORF62* promoter is important because of the central role of IE62 in VZV gene transcription. The upstream region of *ORF62* contains three TAATGARAT-like elements that contribute to the ability of VZV ORF10 protein to transactivate expression of IE62.⁴³⁷ The *ORF62* promoter also contains cAMP-responsive and GA-rich elements that are important for its transactivation. The ORF10 protein forms a complex with two of the TAATGARAT-like elements in the *ORF62* promoter that lack an overlapping octamer-binding motif, but not with the TAATGARAT-like element that possesses an octamer motif. Two cellular proteins, Oct1 and host cell factor (HCF), form a complex with ORF10 and at least one of the TAATGARAT-like elements on the *ORF62* promoter. HCF-1 is critical for activation of immediate-early gene expression by ORF10.⁴⁶¹ The Oct2 cellular protein binds to the TAATGARAT-like elements on the *ORF62* promoter and inhibits ORF10-mediated transactivation. However, ORF10 is dispensable for VZV replication *in vitro* and *in vivo*. Thus, self-regulation of the *ORF62* promoter by IE62 that enters the cell with the infecting virion may be the mechanism that initiates expression of additional IE62 and other IE regulatory proteins.^{541,676} The NF-Y CCAAT box-binding protein and the activating transcription factor/adaptor protein 1 (ATF/AP-1) family also bind to the *ORF62* promoter.³³⁴

ORF61 Protein

ORF61 encodes an essential 467-amino acid protein that is expressed shortly after VZV entry and localizes to the nuclei of infected cells^{595,597} (Fig. 63.6); ORF61 is not detected in the virion tegument. ORF61 protein transactivates putative IE, early and late promoters in transient expression assays,⁴⁴⁴ although not in a T-cell line.⁴⁹⁵ When ORF61 is truncated or mutations of *ORF61* promoter elements restrict its expression, VZV replication is severely compromised.^{653,715} Limiting ORF61 expression by promoter mutations also shows that ORF61 is most important for gE expression. ORF61 dimerization through a domain located at residues 250 to 320 is required for ORF61

regulatory functions and normal replication *in vitro* and in skin xenografts *in vivo*.⁶⁵⁵

ORF61 can either repress or enhance activation of other VZV genes by IE4 and IE62, depending on the cell line and transfection conditions.^{444,460,495,653} The ORF61 N-terminus contains a RING-finger domain that is required for the transactivating activity of the full-length protein.^{163,436} Carboxyl-terminal truncation mutants of ORF61 that retain the RING-finger domain act as dominant-negative transrepressors and reduce the infectivity of viral DNA. Transient expression of ORF61 enhances the infectivity of VZV DNA,⁴⁴⁴ which can be explained by its role in dispersing promyelocytic leukemia (PML) nuclear bodies.⁶⁵⁴ ORF61 is related to HSV ICP0 and can functionally complement an HSV-1 ICP0 deletion mutant.⁴⁴²

IE4

ORF4 encodes the 52-kd essential immediate-early protein IE4.^{95,550} which requires co-expression with *ORF62* for its nuclear localization.¹²¹ IE4 must dimerize for gene activation, and several regions of the protein are required for its transactivation function.^{38,439} Mutation of the KYFKC residues that mediate IE4 dimerization is lethal.⁵⁵⁰ In transient expression assays, IE4 transactivates some, but not all, putative IE, early or late promoters, and also synergizes with IE62 to transactivate promoters of genes from all three kinetic classes. IE4 activation of target genes occurs at both transcriptional⁴⁹⁴ and posttranscriptional levels.¹²² IE4 interacts directly with TFIIB and the nuclear factor- κ B (NF- κ B) p50 and p65 subunits,⁹⁶ and also binds to an underphosphorylated form of IE62.⁵⁸⁵ IE4 may function as a viral mRNA export factor through its RNA binding capacity.⁴⁸¹

IE4 has homology to HSV-1 ICP27 but does not complement an ICP27 mutant.⁴⁴¹ The carboxyl portions of IE4 and ICP27 share the most homology and contain putative zinc-finger domains; however, mutagenesis indicates that several cysteine residues in IE4 are not required for its regulatory activity.⁴⁹⁴ ICP27 cannot complement the growth of an *ORF4* deletion mutant⁹⁵ and, unlike ICP27, IE4 does not appear to have transrepressing activity.^{124,278,441,495}

IE63

ORF63 encodes a 45-kd protein and additional smaller products of 38 and 28 kd.^{120,321,463} IE63 is phosphorylated predominantly in the carboxy-terminal region⁵⁹⁸ by casein kinases I and II, CDK1, and CDK5.^{52,235} Deletion of >90% of both *ORF63* and its duplicate *ORF70* was compatible with very limited VZV replication in melanoma cells; providing IE62 allows an *ORF63* deletion mutant to replicate in U2OS cells, which are also permissive for HSV-1 ICP0 mutants.^{95,580,715} The carboxy-terminal 70 amino acids of IE63 are dispensable, but further deletion of the carboxy-terminus or replacement of some of the serine or threonine phosphorylation sites of the protein with alanines impairs VZV replication^{33,94} and skin infection.³³ IE63 is located primarily in nuclei of infected cells (Fig. 63.6). Phosphorylation of certain amino acids of IE63 is important for its cellular localization when expressed alone, but not when expressed in the context of the whole virus.^{52,94} When expressed alone in neurons, IE63 nuclear import requires ORF61.⁶⁴⁸ IE63 binds to IE62 and the two proteins exhibit some colocalization in infected cells; IE63 also binds to the cellular RNA polymerase II³⁸² and to antisilencing protein 1, interfering with its histone binding capacity.⁸ IE63 is reported to repress expression of VZV promoters in some transient transfection

assays,^{52,285,339,382} but IE62 is the only viral gene product that is significantly reduced in cells infected with an IE63-null mutant.²⁶⁷ IE63 also transactivates the EF-1 α promoter in the absence of other viral proteins.⁷²⁰ IE63 is the homolog of the HSV-1 U_S1.5 protein, which is expressed co-linearly with HSV-1 ICP22 (U_S1).³³

Replication of Viral DNA

Replication Proteins

VZV encodes homologs of each of the seven HSV-1 genes required for origin-of-replication (ori)-dependent replication of viral DNA (Table 63.1); however, the minimal repertoire of genes needed for VZV DNA replication is not known.

DNA Polymerase

ORF28 encodes the large subunit of the VZV DNA polymerase.¹¹⁹ The VZV DNA polymerase has been partially purified from infected cells and requires magnesium for maximal activity. Unlike the cellular polymerase, the VZV enzyme is sensitive to phosphonoacetic acid, although less so than HSV-1 DNA polymerase,³⁰⁵ and its activity is enhanced in the presence of ammonium sulfate.^{399,420} *ORF16* is predicted to encode the small subunit processivity factor of the VZV polymerase.

DNA Binding Proteins

ORF29 encodes a 130-kd protein that localizes to nuclei of infected cells via a noncanonical nuclear localization signal^{91,249,586} (Fig. 63.6). Both *ORF29* and its HSV-1 homolog, ICP8, bind ssDNA, although the VZV protein binds with lower efficiency²⁴⁹ and cannot substitute for ICP8.⁶⁶⁵ *ORF29* binds to the *gI* promoter *in vitro*.⁵³ Furthermore, *ORF29* protein increases or decreases transactivation of a reporter gene by IE62, depending on the cell line.⁵³ *ORF29* protein is secreted from VZV-infected cells and can be endocytosed by neurons.¹⁵ *ORF29* is also part of a complex that binds to a sequence in the Ori_s, which functions as a negative regulator of VZV DNA replication.³¹⁸

ORF51 encodes the ori binding protein.⁶⁰¹ The carboxyl portion of *ORF51* protein binds *in vitro* to three DNA sequence motifs in the VZV ori with similar affinities.⁷⁹ As in the HSV-1 homolog, UL9, a CGC triplet in the VZV ori is required for *ORF51* binding. *ORF51* can substitute for HSV-1 UL9 in an origin-dependent HSV DNA replication assay⁶⁶⁵ and can partially complement growth of an HSV-1 UL9-null mutant.⁸⁰ VZV DNA binds five other proteins of unknown identity or function, ranging from 21 to 175 kd in size.⁵³²

Genome Replication

By analogy with HSV, VZV DNA replication is presumed to occur in four stages.¹¹⁷ First, the linear DNA molecule circularizes shortly after virion entry. This event is facilitated by the complementary unpaired nucleotides at each 3' end of the VZV genome. The presence of a fused UL-US joint, as demonstrated by cloning of VZV genomic DNA, supports this concept. The second stage involves replication of the circular genomic template. Isomerization of progeny genomes is thought to occur by homologous recombination between the inverted repeats. Third, replication of the circular molecule generates head-to-tail concatemers, probably by a rolling-circle mechanism (Fig. 63.3).⁶⁰⁰ Fourth, these concatemers are

cleaved by sequence-specific nucleases to generate linear DNA for packaging into virions.

Both the VZV and HSV-1 genomes contain AT-rich and GC-rich sequences near their leftward and rightward termini, respectively. Since these sequences are implicated in cleavage and packaging of HSV-1 DNA, the equivalent VZV sequences may serve similar roles. Because VZV exists predominantly as two isomers, 95% of cleavage appears to occur at one U_L-U_S junction, but occasionally cleavage at the other UL-US joint yields the two minor isomers.³²⁷

The VZV genome contains duplicate ori_s between ORFs 62 and 63 in the IRS and between ORFs 70 and 71 in the TRS^{119,600} (Fig. 63.3). Transfection of cells with plasmids containing the VZV ori_s followed by VZV infection results in replication of these plasmids. The VZV genome does not have a homolog of the HSV-1 ori_L sequence.

The VZV ori_s contains a near-perfect 45-bp palindrome with the sequence (TA)₁₇ at its center. Mutations of the palindrome impair replicative activity. The VZV ori_s also includes a GA-rich region and three binding sites for the VZV origin-binding protein, ORF51. These sequences are CGTTCGCACTT (also found in both the ori_s and the ori_L of HSV-1)⁶⁰⁰ and CATTCGCACTT. Unlike the HSV ori_s and the ori_L, all three VZV ori-binding protein sites are upstream of the palindrome on the same strand and are oriented in the same direction.⁷⁹ Dpn1 DNA replication assays indicate that the 45-bp palindrome and the sequence CGTTCGCACTT closest to the palindrome are essential for replication, whereas the sequence CATTCGCACTT contributes additional activity but is not essential.⁶⁰¹

Viral Enzymes

Thymidine Kinase

ORF36 encodes a viral thymidine kinase (TK)⁵⁵⁷ dispensable for VZV replication. Since the VZV enzyme has more deoxycytidine than TK activity, it is more accurately a deoxypyrimidine kinase.⁴⁷¹ The enzyme is a 70-kd homodimer composed of two 35-kd subunits. It is most active *in vitro* at a higher pH and has broader substrate specificity than its cellular homolog.⁸³ VZV TK is more thermostable and more susceptible to inhibition by deoxythymidine triphosphate than is HSV-1 TK.⁴⁷¹ TK phosphorylates and thereby activates acyclovir and its analogs. Most acyclovir-resistant VZV isolates have point mutations in the TK gene near the adenosine triphosphate (ATP) or thymidine-binding sites or have mutations that result in a truncated protein.^{435,556} Differences between the structures of VZV and HSV TK may explain some differences in their substrate activities.⁴⁸

Ribonucleotide Reductase

ORFs 18 and 19 encode proteins homologous to the small and large subunits of HSV-1 ribonucleotide reductase, respectively.¹¹⁹ VZV ribonucleotide reductase has enzymatic activities similar to those of its HSV-1 homolog. Unlike cellular ribonucleotide reductase, the VZV and HSV-1 enzymes are not inhibited by increased intracellular levels of deoxyribonucleotides.⁵⁸³ Inhibition of VZV ribonucleotide reductase with small molecules enhances the antiviral activity of acyclovir, presumably by decreasing the intracellular pool of deoxyribonucleoside triphosphates and increasing the concentration of acyclovir triphosphate. Deletion of *ORF19* from the viral genome abolishes viral ribonucleotide reductase activity, impairs the growth of the virus *in vitro*, and potentiates inhibition of replication by acyclovir.²⁵⁴

ORF47 and ORF66 Protein Kinases

As components of the virion tegument, ORF47 and ORF66 are likely to be important for activation of regulatory proteins in the newly infected cell. *ORF47* encodes a 54-kd serine-threonine protein kinase and is a tegument component. ORF47 phosphorylates both acidic and basic proteins, but with a marked preference for acidic amino acids, using both ATP and guanosine triphosphate (GTP) as phosphate donors; it also phosphorylates casein kinase II.^{316,462} The HSV homolog, UL13, has a similar catalytic domain.⁵⁹⁶ ORF47 protein autophosphorylates and also phosphorylates viral proteins ORF32,⁵²¹ IE62,^{317,463} IE63,³¹⁷ gI,³¹⁶ and gE³¹⁵ but is not required for phosphorylation of gE, IE62, or IE63 in VZV-infected cells.^{255,317} ORF47 binds to IE62 through an N-terminal domain.⁴⁴ The N-terminal DYS motif is required for ORF47 kinase activity which, if disrupted, results in nuclear retention of ORF47 and IE62. Deletion of ORF47 does not alter plaque formation²⁵⁵ but does lead to accelerated gE expression on membranes and cell–cell spread.³¹⁶ However, even though plaques appear normal in the absence of ORF47, the protein and its kinase activity are required for efficient VZV virion assembly and transport to cell surfaces.⁴⁴ ORF47 is important for T cell and dendritic cell infection *in vitro*, is important for skin infection, and essential for T-cell tropism *in vivo*.^{44,271,582}

ORF66 encodes a 393-amino acid phosphoprotein present in the virion tegument and expressed in the nucleus, in puncta surrounding nucleoli, and in cytoplasm of infected cells.^{153,560} ORF66 is a serine-threonine protein kinase that autophosphorylates⁵⁵⁹ and phosphorylates IE62. The ORF66 catalytic domain (residues 93–378) is homologous to the HSV-1 US3 and other members of this protein kinase superfamily.¹⁵² IE62 phosphorylation by ORF66 determines its late accumulation in the cytoplasm of infected cells, where packaging into virions occurs.³²² Mutagenesis of the glycine 102 residue in a highly conserved, glycine-rich ATP-binding motif in this domain blocks ORF66 kinase function.⁵⁶⁰ ORF66 also phosphorylates the cellular nuclear matrix protein, matrin 3, which may modulate RNA processing^{157,158} and targets histone deacetylases to promote transcription.⁶⁴⁷ ORF66 is dispensable for replication *in vitro* and in human skin xenografts in the SCID mouse model; however, the absence of ORF66 or disruption of its kinase activity leads to impaired growth and production of virions in human T cells in xenografts.^{428,559,560} VZV infection of primary corneal fibroblasts also requires ORF66 functions.¹⁵⁹

Other Viral Enzymes

ORF8 encodes a deoxyuridine 5′-triphosphate nucleotidohydrolase (dUTPase), which hydrolyzes deoxyuridine 5′-triphosphate (dUTP) to deoxyuridine 5′-monophosphate (dUMP) and pyrophosphate.⁵³⁷ *ORF8* is not required for growth *in vitro* nor is *ORF13*, which encodes the viral thymidylate synthetase.¹⁰⁰ *ORF59* encodes the VZV uracil DNA glycosylase that removes uracil residues incorporated into newly synthesized DNA strands.⁵²² This protein is not necessary for replication in cell culture. VZV-infected cells express a DNase activity⁸³ thought to be encoded by ORF48, the homolog of HSV-1 UL12.

ORF33 encodes the precursor of the VZV serine protease, which is cleaved autocatalytically at two sites.^{184,408} The mature 31-kd protease is the amino-terminal cleavage product. The active form of the protease is predicted to be a homodimer. The VZV protease crystal structure is similar to that of the

cytomegalovirus (CMV) protease.⁵¹³ A serine and two histidines comprise the catalytic site of the VZV protease; mutation of either one of these histidines in the protease precursor protein prevents self-cleavage.

ORF17 encodes the homolog of the viral host shut-off protein encoded by HSV-1 UL41. *ORF17* is dispensable for replication, but deletion of this gene yields a temperature-sensitive mutant. ORF17 protein induces RNA cleavage much less effectively than does its HSV-1 homolog,⁵⁵¹ and the host shut-off function in VZV-infected cells is correspondingly less efficient.

The *ORF9-12* Gene Cluster

ORF9 encodes an essential protein present in the virion tegument that interacts with IE62 and is phosphorylated by ORF47.^{76,584,621} *ORF9A* encodes the putative 7-kd gN protein located in the membranes of infected cells.⁵³⁷ Although this protein is not required for replication, blocking ORF9A expression impairs syncytia formation.

ORF10 encodes a 50-kd protein that is incorporated into the viral tegument³²⁴ and localizes to the *trans*-Golgi network in infected cells. ORF10 is the homolog of HSV-1 VP16, but unlike its HSV-1 counterpart, it is dispensable for replication.^{77,102} ORF10 complements an HSV VP16 mutant and enhances the infectivity of transfected VZV virion DNA.⁴⁴³ ORF10 transactivates the *ORF62* promoter, but not the *ORF4* or *ORF61* promoter. ORF10 forms a complex with TAATGARAT-like sequences and Oct1 and HCF to transactivate the ORF62 promoter.⁴³⁷ ORF10 is important for replication in human skin, but not in T-cell xenografts in SCID mice.⁷⁷

ORF11 is expressed as a 118-kd polypeptide present in the virion tegument and in the nucleus and cytoplasm of infected cells. ORF11 alone has little effect on VZV gene transcription, but IE4, IE62, IE63, and gE proteins are reduced if ORF11 is deleted from the viral genome.^{75,76} ORF11 functions as an RNA binding protein with the binding region in the first 22 residues of the protein. RNA binding is conserved among the UL47 alphaherpesviruses homologs. ORF11 is critical for VZV infection of human skin xenografts, but its RNA binding function is not required.⁷⁵

ORF12 encodes a predicted tegument protein *ORF12* has effects on all cycle progression by activation of the P13 kinase/Akt pathway.^{371a} It is dispensable for replication *in vitro* and in skin xenografts *in vivo*.⁷⁶

Nucleocapsid Proteins

Three forms of nucleocapsids are found in VZV-infected cells.²⁴³ Immature B capsids lack viral DNA and contain 32- and 36-kd proteins, presumed to be the mature viral protease and assembly proteins, respectively, present in the nuclear matrix of VZV-infected cells.¹⁷⁷ Mature C capsids contain viral DNA but lack the 32- and 36-kd proteins. Intermediate B/C capsids are thought to contain the VZV genome and the 32- and 36-kd proteins.

ORF40

ORF40 encodes the 155-kd major nucleocapsid protein that localizes to the nuclei of infected cells. A monoclonal antibody to this protein cross-reacts with the HSV-1 UL19 homolog.⁶³³

ORF33

ORF33.5, located in the 3' portion of the *ORF33* gene, encodes the 40-kD precursor of the VZV assembly protein. The mature 37-kD assembly protein is released after cleavage from its precursor by the VZV protease.^{408,506} The assembly protein is presumed to provide a scaffold for nucleocapsid assembly. When expressed *in vitro*, ORF33.5 forms long, hollow rods that accumulate predominantly in the nuclei of cells.⁵⁰⁶

ORF23

ORF23 encodes a conserved capsid protein, called VP26 (UL35) in other alphaherpesviruses, which is expressed as a late protein^{74,525} (Fig. 63.6). Unlike VP26, ORF23 localizes to nuclei through an SRSRVV motif in the carboxy-terminus and mediates nuclear import of ORF40, the major capsid protein. ORF40 is also translocated by ORF33.5. ORF23 is not essential for VZV replication, but deletion disrupts capsid assembly *in vitro*. ORF23-mediated nuclear transport of the major capsid protein is necessary in skin xenografts *in vivo*, and the ORF33.5 interaction with ORF40 does not provide a redundant capacity for this function.

ORF21

ORF21 encodes a 115-kD protein located in the nucleocapsid.³⁸³ The protein localizes to both the nucleus and the cytoplasm of infected cells. ORF21 is essential for VZV replication, and its HSV-1 homolog, UL37, cannot complement its absence *in vitro*.⁶⁹⁰

Other Putative Late Proteins

ORF35 encodes a protein that localizes to the nuclei of infected cells. A mutant deleted for this gene is impaired for cell-to-cell spread and for infection of human skin and T-cell xenografts in SCID mice.²⁸¹ Deletion of *ORF64* results in virions that induce extensive cell fusion with large syncytia.⁵⁸⁰ *ORF65* encodes a 16-kD virion protein that localizes to the Golgi apparatus of virus-infected cells⁹⁹; it is dispensable for VZV infection of human T cells and skin xenografts in SCID mice.⁴⁶⁶

Glycoproteins

VZV glycoproteins are major constituents of the viral envelope that are also expressed on intracellular membranes and have critical interactions with other viral and cellular proteins during VZV entry, replication, and cell–cell spread.

Glycoprotein B

gB (formerly gpII), encoded by *ORF31*, is the most highly conserved of the herpesvirus glycoproteins. In addition to its presumed role in attachment and entry, gB expression along with gH/gL is sufficient to induce cell fusion.^{609,640} Unlike HSV gB, VZV gB has a furin recognition motif at residues 491 to 494 and is cleaved into two polypeptides that are bound together by disulfide residues. Thus, under nonreducing conditions, gB migrates in gels as a 140-kD protein, whereas under reducing conditions, gB resolves as two proteins of 60 and 70 kD. Virion morphology, protein localization, plaque size, and replication kinetics are not altered by mutations eliminating gB furin cleavage, but furin cleavage is necessary for normal VZV replication in human skin xenografts *in vivo*.⁴⁷³ gB contains two tyrosine-based motifs in its cytoplasmic domain that are required for endocytosis to the Golgi network^{257,259}; gB asso-

ciates with clathrin during endocytosis. The carboxy-terminal 36 amino acids of gB are required for normal trafficking to the cell surface.²⁵⁸ gB has both N- and O-linked sugars and is sialylated, sulfated, and palmitylated.^{150,221,234,429} An immunoreceptor tyrosine-based inhibition motif has recently been identified in the gB cytoplasmic domain that regulates cell fusion and skin pathogenesis.^{474a}

Glycoprotein C

gC (formerly gpV), encoded by *ORF14*, is dispensable for growth in cell culture. Because the number of R2 repeats in the gC coding sequence differs, gC varies from 80 to 170 kD. The gC endodomain consists of only six amino acids. gC is heavily glycosylated, with about one-third of its molecular weight resulting from N- and O-linked glycosylation.²²² gC transcription and translation is delayed compared to other VZV glycoproteins, with little VZV gC detected until 72 hours after infection. The quantity of gC transcripts and protein produced also varies depending on the VZV isolate.^{326,328,370} In contrast to cultured cells, skin lesions show abundant gC in a pattern consistent with virion envelope expression⁵⁹⁹ (eFig. 63.2). This difference may be related to the limited production of infectious virus particles *in vitro*.

Glycoprotein E

gE (formerly gpI) encoded by *ORF68* is an 85- to 100-kD protein. Unlike its homologs, VZV gE is an essential protein^{421,431} and has a unique N-terminus of 188 residues necessary for VZV replication.⁴² Although gE has been considered to be a late gene product, it is detectable in a Golgi-like cytoplasmic distribution by 4 hours and is expressed extensively on plasma membranes by 9 hours⁵²⁵ (Fig. 63.6). While gE homologs are encoded within the US, *ORF68* extends into the repeat regions. gE contains both N- and O-linked sugars, is heavily sialylated^{221,431} and is modified by myristylation, palmitylation, and sulfation.¹⁵⁰ Its monomeric form is phosphorylated at serine and threonine residues by casein kinase II, whereas the homodimeric form of gE is phosphorylated by a tyrosine kinase.^{475,699} gE binds the Fc receptor of human immunoglobulin.³⁷² Expression of gE in epithelial cells induces formation of tight junctions.⁴²²

After synthesis and maturation in the Golgi apparatus, gE is transported to the cell membrane. The short gE cytoplasmic domain (62 amino acids) has an endocytosis motif, YAGL, a TGN-targeting AYRV tyrosine motif and an acidic amino acid-rich phosphorylation motif.^{221,315,426} The AYRV motif and the acid patch are required for gE transport.^{717,718} Endocytosis to the TGN requires the YAGL motif, which allows recycling of gE through endosomes back to the cell membrane.⁴⁷⁶ Phosphorylation of gE by the ORF47 protein kinase is necessary for endocytosed gE to traffic to the TGN. In cells infected with a mutant unable to express ORF47, gE accumulates on cell membranes.^{315,316} gE endocytosis from the plasma membrane is necessary for incorporation into virions.⁴⁰² The YAGL endocytosis motif is required for virus replication; the AYRV motif is important for VZV replication in human skin and T-cell xenografts in SCID mice.⁴²⁶

Residues in the unique gE N-terminus are important for normal gE expression, secondary envelopment and cell-to-cell spread, and are essential for skin infection.⁴² Residues within amino acids 27 to 90 are necessary for gE binding to insulin-degrading enzyme (IDE), normal cell-to-cell spread

in vitro^{1,7,41,42} and for virulence in skin xenografts, but not for virus entry into T cells.⁴² Nonglycosylated immature gE binds to IDE in the ER.⁶⁶ The unique gE residues 51 to 187 are necessary for VZV infection of skin as well as T cells. VZV-MSP is a naturally occurring mutation in the unique gE N-terminus, changing the amino acid of codon 150 from aspartic acid to asparagine. The mutant shows altered cellular egress and enhanced cell–cell spread *in vitro* and in skin xenografts.⁵⁴⁷

Correct gE trafficking and maturation requires heterodimerization of gE with gI.^{320,372,698} gE/gI heterodimer formation depends on the cysteine-rich region (amino acids 208–236) also present in gE encoded by other alphaherpesviruses. The capacity of gE to bind to gI is a major determinant of VZV virulence in skin xenografts, indicating that cell–cell fusion and polykaryocyte formation depends on this interaction.⁴¹ Disrupting gE/gI heterodimer formation also results in aberrant VZV infection of dorsal root ganglion (DRG) xenografts, causing severe tissue damage despite impaired cell-to-cell spread. In contrast, mutations of the gE AYRV trans-Golgi localization motif and blocking gE/IDE binding did not alter VZV neurovirulence in DRG xenografts.⁷¹¹

Glycoprotein L

gI (formerly gpIV), encoded by *ORF67*, is a 58- to 62-kd glycoprotein that contains N- and O-linked sugars.^{221,431,697} gI heterodimer formation with gE requires residues 105 to 125 and four highly conserved cysteine residues that are also necessary for gI structure and virion incorporation.⁴⁷⁴ gI is not required for VZV replication in cultured human cells but is required in Vero cells. Deleting gI impairs efficient cell-to-cell spread of virus, adsorption to cells, and syncytia formation *in vitro*. gI is essential for infection of human skin and T-cell xenografts in SCID mice.^{97,395,425} Mutations that alter Sp1 or USF binding sites in the gI promoter reduce gI expression and impair infection of human T-cell and skin xenografts in SCID mice, but not in cultured cells.²⁸⁰

The gI cytoplasmic tail is phosphorylated by a cyclin-dependent kinase⁷⁰²; the phosphorylation sites are not required for VZV skin infection. A threonine residue in the gI endo-domain targets gI to the TGN when expressed alone in cultured cells, although gI is more rapidly localized to the TGN in the presence of gE.^{6,657} The carboxy-terminal domain of gI is required for envelopment of VZ virions in the TGN.⁶⁵⁶ While gI is also endocytosed from the cell surface and has a methionine-leucine internalization motif in its cytoplasmic tail, the gE-gI complex undergoes endocytosis more efficiently than does gE or gI alone.^{6,477} VZV gI is required for normal maturation of gE and for efficient distribution of gE to the cell surface.

Glycoprotein H

gH (formerly gpIII), the product of *ORF37*, is a 118-kd glycoprotein that contains N-linked but not O-linked sugars and is sialylated and sulfated.^{150,221,222,306,430} gH forms a heterodimer with gL. gH is secreted into the medium of cultured cells.⁵⁷⁴ gH requires gL for processing in the Golgi network and transport to the cell surface.^{144,171,400} The short cytoplasmic tail of gH contains a tyrosine-based motif (YNKI) that mediates clathrin-dependent endocytosis of gH in infected cells.⁴⁸⁸ Endocytosis of gH results in reduced cell surface expression and decreased cell–cell fusion; gE enhances fusion mediated by gH.⁴⁰¹

Co-expression of gH with either gE or gI allows transport of an immature form of gH to the cell surface, but this form is not fusogenic.¹⁴³ gH forms a complex with gE in virus-infected cells and during incorporation into virions.^{402,366}

The gH ectodomain has three predicted subdomains—DI, DII, and DIII, based on homology with HSV gH—that have specific functions in cell fusion and VZV pathogenesis as demonstrated by site-directed mutagenesis.⁶⁴⁰ The extreme N-terminal residues in DI are important for skin tropism, T-cell entry, and fusion. DII helices and a conserved disulfide bond are essential for gH structure and VZV replication. Disulfide bonds and a bridging strand in DIII are required for the structural stability of this domain and are critical for membrane fusion. The biologic importance of gH DIII function during VZV replication is evident since a naturally occurring compensatory mutation was acquired during VZV replication when the ⁷²⁴CXXC⁷²⁷ motif was mutated; this DIII mutation stabilized the bridging strand and rescued both a replication-deficient virus and a lethal cysteine mutation that disrupted the fusion function of gH.⁶⁴⁰

Glycoprotein L

gL (formerly gpVI), encoded by *ORF60*, is a 20-kd glycoprotein that forms a complex with gH, acting as a chaperone that associates with the immature but not the mature form of gH.¹⁴⁴ gL is thought to be glycosylated with an N-linked oligosaccharide.¹⁴⁴ Whereas gH requires gL for its maturation, gL is fully processed in the absence of gH. When expressed alone or with gH, gL accumulates only in the cytoplasm.¹⁴³ gL contains an ER-targeting sequence and is recycled between the ER and the Golgi network.¹⁴³ Co-expression of gH and gL supports syncytia formation, whereas expression of either protein alone does not.^{222,144}

Glycoprotein K

gK, encoded by *ORF5*, is a 40-kd glycoprotein containing N-linked sugars and is required for VZV replication.⁴²³ Overexpression of gK in a cell line inhibited syncytia formation by wild-type virus. HSV gK cannot complement growth of gK-deleted VZV.

Glycoprotein M and Glycoprotein N

gM, encoded by *ORF50*, is a 435-amino acid membrane glycoprotein. *ORF50* has one full-length transcript that produces gM and three alternatively spliced transcripts that are rarely translated *in vitro*.^{434,694} gM is predicted to contain eight transmembrane domains, an N-glycosylation site, and a cysteine residue in the first ectodomain. gM is 42 to 48 kd in infected cells and virus particles; a 37-kd precursor, not yet modified by N-linked oligosaccharides, is present in infected cells. gM localizes to the Golgi and endosomes, where it may be incorporated into the virion envelope. The functions of gM are not defined, although its presence in virus particles suggests a role in viral entry and virion maturation.⁴³⁴ As observed in other herpesviruses, gM forms a complex with gN through a disulfide bond; the interaction with gN is necessary for gM maturation, transport and virion incorporation. *ORF50* is dispensable, but gM deletion mutants have impaired plaque formation and spread, with vacuoles containing electron-dense material appearing in the cytoplasm.⁶⁹⁴ An *ORF50* deletion mutant did not replicate in melanoma cells.⁷¹⁵

Assembly and Release

Infectious VZV progeny are synthesized and released efficiently from cells infected *in vivo* (see Pathogenesis and Pathology). Fluid aspirated from varicella or zoster vesicles contains large numbers of infectious cell-free virions.^{69,615} In contrast, VZV is highly cell associated in cultured cells.²⁴⁵ Low titers of infectious cell-free virus can be recovered by sonicating VZV-infected cells,²²⁴ but yields are only 1 to 2×10^9 particles per milliliter and the particle-to-infectivity ratio is 40,000:1⁶⁴ compared to 60:1 for HSV-2. Moreover, virions remain attached to cell membrane fragments. VZV virions are usually enclosed in membrane-lined vacuoles within the cytoplasm. Viewed by transmission electron microscopy (TEM), the virions appear to be degraded during transit through the cytoplasm, while analysis by three-dimensional electron microscope (EM) tomography shows that most particles are intact.⁵²⁸

Because VZV replication in cultured cells is expected to differ from that in differentiated cells in the human host, any model of assembly and egress derived from *in vitro* observations will be incomplete. However, the current model is that nucleocapsids transit the inner and outer nuclear membranes for delivery into the cytoplasm in a process that involves envelopment, fusion and de-envelopment.¹⁹³ VZV ORF24 and ORF27 are likely to have functions in nuclear egress similar to those of their respective HSV homologs, UL31 and UL34. In the cytosol, the naked nucleocapsids are enveloped by cisternae of the TGN. The cisternae are decorated with VZV-encoded glycoproteins with their cytoplasmic tails extending into the cytosol. Tegument proteins adhere to the cytosolic faces of TGN membranes (Fig. 63.2). The naked nucleocapsids attach to the tegument and invaginate into the cisternae. In cultured cells, these vesicles are usually diverted to prelysosomes, where they are subjected to degrading enzymes (Fig. 63.5). Many nascent particles enter late endosomes, probably because some of their envelope proteins are glycosylated with mannose-6-phosphate residues.^{82,180} Mannose-6-phosphate side chains render the evolving particles susceptible to binding and uptake by lysosomes bearing the cation-independent mannose 6-phosphate receptor (MPR^{ci}).⁸² Cell lines deficient in MPR^{ci} release cell-free VZV more efficiently than other cultured cells. This latter feature of the model of VZV assembly and release implies that an alternative secretory pathway is operative in some cell types *in vivo* to allow virus egress without lysosomal degradation (Fig. 63.5). Superficial epidermal skin cells, which lack MPR^{ci}, show a pattern of VZV maturation resembling that seen in cells deficient in this receptor.⁸²

Syncytia Formation

In cultured cells, VZV induces foci of rounded, refractile cells in human diploid cells. Cell-cell fusion with formation of large syncytia is a hallmark of VZV replication in cell culture (Fig. 63.7), becoming detectable at about 9 hours after infection of melanoma cells.⁵²⁵ Syncytia formation involving about 75% of the monolayer is observed by 48 hours, and the fused cells detach from the surface at about 60 hours. These multinucleated giant cells have enlarged nuclei, abnormal nucleoli and marginated chromatin. In addition to its importance in cultured cells, syncytia formation is important for VZV pathogenesis in skin, where polykaryocytes are prominent. VZV also induces the fusion of neurons and satellite

cells in DRG.³²⁷ In contrast, VZV does not cause fusion of T cells; instead, spread in T-cell xenografts is associated with the release of infectious cell-free virions.^{427,428} VZV also induces the formation of “viral highways” in which viral particles decorate the surface of infected cells, especially within the syncytia and on filopodia^{65,221,245} (Fig. 63.7), and an increase in cell surface virions is associated with more rapid cell-to-cell spread.⁵⁴⁷

The gB/gH/gL complex, which is presumed to function in fusion of the viral envelope with the cell-surface membrane during entry, is essential for cell fusion and syncytia formation.⁶⁴⁰ Residues in gH domain III are necessary for cell-to-cell fusion and virulence in skin xenografts. Formation of typical VZV syncytia also requires gE/gI heterodimerization and functions that depend on the unique gE N-terminus.^{41,42} Deleting gI (ORF67) or reducing its expression by promoter mutations results in a small-plaque phenotype with distorted polykaryocyte formation.^{97,395} Syncytial formation is also reduced if the products of both ORF8 and ORF9A are not expressed.⁵³⁷ Conversely, typical syncytial formation can be retained *in vitro* even with mutations that severely disrupt VZV virion formation, such as those blocking ORF47 expression or eliminating its kinase activity; the deficiency is evident only by markedly impaired skin infection.^{47,48}

Replication in Specialized Cell Types in Culture

VZV replication and gene requirements have been studied *in vitro* using primary human cells, cell lines, and organ cultures that reflect the tropisms of the virus *in vivo* (Fig. 63.8). Human tonsil T cells are highly permissive for VZV replication,³⁴³ whereas VZV infects T cells at low frequencies in peripheral blood mononuclear cell (PBMC) cultures from adult peripheral blood or cord blood⁵⁸²; infection can be increased by T cell activation.³³⁶ VZV has only limited capacity to replicate in transformed human B cells.³³⁶ VZV replicates in immature but not in mature dendritic cells.^{2,273}

Skin organ cultures are permissive for VZV. Deleting ORF 7, 10, 14, and 47 disrupts VZV infection of skin organ cultures but not of cultured cells, whereas deletions of ORF 0, 18, 19, 23, 32, 35, 49, and 68 affect both.⁷¹⁵ Infected keratinocytes release cell-free virus *in vitro* but infectious virus yields are low, whereas *in vivo* infection yields high titers.¹⁹⁰

VZV infects dissociated cells cultured from nervous system tissues, including both neuronal and nonneuronal cells (Schwann cells and astrocytes).²⁶⁶ VZV also infects neurons and supporting cells in explanted intact ganglia⁵⁸⁹ and neurons derived from human embryonic stem cells.⁴⁰⁴ Infection of human fetal neurons with a clinical VZV isolate resulted in sevenfold more virus replication compared to infection with the Oka vaccine.⁵⁷⁹ Infection of differentiated neurons in culture with cell-free VZV did not produce cytopathic effects or infectious virus, although VZV DNA, virus-specific transcripts and protein, including gE, were found several weeks later.⁵¹⁰

VZV Effects on the Host Cell

Cell Protein Synthesis, Cell Cycle Changes, and Other Effects

Although ORF17 encodes a homolog of the HSV virion host shut-off (VHS) protein, ORF17 is not present in the tegument and has little impact on host protein synthesis.⁵⁵¹

FIGURE 63.7. Varicella-zoster virus (VZV) infection of human cells *in vitro*.

A: An early focus of VZV infection in a monolayer of human fibroblasts stained with hematoxylin and eosin (H&E, × 240)

B: A multinucleated cell containing intranuclear inclusion bodies from a monolayer of VZV-infected human fibroblasts (H&E, × 2,600). **C–E.** Microstructural composition of “viral highways,” the distinctive linear patterns from which VZV emerges as complete and aberrant viral particles

(white arrows) and cellular projections (black arrows) of 70- to 100-nm diameter (by transmission electron microscopy): **C:** five viral particles and several projections; **D:** one elongated projection surrounded by portions of other projections;

E: viral highway covered by cellular projections with viral particles in between (by scanning electron microscopy). (Adapted from Breuer J. VZV molecular epidemiology. *Curr Top Microbiol Immunol* 2010;342:15–42.)

However, VZV infection dysregulates and arrests the cell cycle in fibroblasts (eFig. 63.3), an effect characterized by high levels of expression of cyclins A, B1, and D3 without extensive synthesis of cellular DNA.^{356,424} Cyclin-dependent kinase (CDK) activity is essential for VZV replication; CDK1 phosphorylates IE62 and is present in virions.³⁵⁵ VZV replication may be associated with activation of the DNA damage response, leading

to cell-cycle arrest. VZV may also activate transcription factors and increase cell-cycle regulatory proteins through the mitogen-activated protein kinase pathways, extracellular-regulated kinase (ERK) and c-Jun N-terminal kinase (JNK). p27, p53, and ATM kinase are other examples of host regulatory proteins induced in infected cells. VZV infection also alters the organization of actin in the cell.³⁴⁵

FIGURE 63.8. Varicella-zoster virus (VZV) infection of specialized cell types. **A:** VZ virions in T cells infected with pOkα at 14 days postinoculation, showing intranuclear capsids (*upper*) and complete virions within a large cytoplasmic vesicle (*lower*). **B:** Dendritic cells two days after infection and stained with monoclonal antibody to CD1a (*arrowheads*) and rabbit antibody to IE4 (*arrows*). **C:** Immunohistochemistry of VZV-infected skin organ cultures on day 6 after inoculation, stained with human anti-VZV serum and visualized with Vector Red and hematoxylin counterstain. **D:** Human embryonic stem cell–derived neurons infected with recombinant VZV expressing green fluorescent protein fused to ORF23. Inflammasome Formation

In response to VZV infection, host cells mount an innate response through pattern recognition and the formation of the nucleotide-binding domain and leucine-rich repeat-containing/pyrin domain–containing 3 (NLRP3) inflammasome. NLRP3 protein recruits the adaptor apoptosis-associated speck-like protein (ASC) and caspase-1, resulting in processing of the proinflammatory cytokine interleukin (IL)-1β by activated caspase-1.⁴⁷⁰ NLRP3 is also upregulated in VZV-infected skin xenografts *in vivo*.⁴⁷⁰

Interference with Intrinsic Antiviral Responses

CELL SIGNALING.

Activation of several cellular pathways that support antiviral responses is targeted for inhibition by VZV. ORF66 interferes with the induction of phosphorylated signal transducer and activator of transcription 1 (STAT1) after exposure to interferon gamma (IFN-γ) in VZV-infected T cells and fibroblasts.⁵⁵⁹ VZV also interferes with nuclear factor (NF)-κB activation in cultured fibroblasts and in epidermal cells in skin xenografts *in vivo* by rapidly sequestering p50 and p65 in the cytoplasm and by inhibiting degradation of the NF-κB inhibitor, IκBα.²⁹³ However, VZV infection of human monocytes induces NF-κB and IL-6 through the toll-like receptor 2 pathway.⁶⁵¹ VZV also

inhibits the expression of STAT 1-α and Janus kinase 2 (JAK2) proteins as well as the transcription of IFN regulatory factor 1 and the major histocompatibility (MHC) class II transactivator, mediating IFN-γ signal transduction.

In contrast to its inhibition of STAT1, VZV induces STAT3 activation in T cells and fibroblasts, as is also observed in cells infected with the oncogenic herpesviruses KSHV and EBV.⁵⁶⁸ STAT3 phosphorylation requires infectious VZV and is a direct rather than a cytokine-mediated effect. STAT3 phosphorylation leads to the induction of the cell protein survivin *in vitro* and in infected skin cells (Fig. 63.9). Inhibition of STAT3 phosphorylation diminishes VZV virulence in skin xenografts and survivin inhibition reduces VZV replication. Since STAT1 and STAT3 activation are inversely activated signaling events, VZV-mediated STAT3 activation may enhance replication indirectly by blocking STAT1-mediated innate responses and directly by promoting survival of infected cells through enhanced survivin expression (Fig. 63.10).

INTERFERON AND INTERFERON-REGULATED RESPONSES.

As is true of other viruses, IFNs significantly inhibit VZV. The induction of the type I IFN pathway is initiated by IFN-β primarily through activation of IFN response factor (IRF)-3, leading to IFN-α production. VZV blocks IFN-β production efficiently and downregulates transcription of IRF3-dependent

FIGURE 63.9. Effects of varicella-zoster virus (VZV) on the host cell. **A:** Kinase-dependent and specific downregulation of surface MHC-I by ORF66. MRC5 cells were infected with an adenovirus vector expressing ORF66-GFP (Ad.GFP-66) or a kinase mutant (Ad.GFP-66kd) with a tet-off construct (Ad.Tet-Off) with or without doxycycline; at 36 hours, cells were stained with fluorophore-conjugated antibodies to MHC-I and transferrin receptor (TfR1) or isotype controls and analyzed by flow cytometry. **B:** STAT3 activation and induction of survivin in VZV-infected skin sections obtained 21 days after infection and analyzed by immunohistochemistry. *Upper two panels:* Sections were probed with antibodies to VZV IE63 to identify foci of infected cells and pSTAT3; expression was detected with DAB (brown) chromogen and hematoxylin counterstain. *Lower panel:* VZV-infected skin sections were stained with antibodies to gE (red) and survivin (green) and examined by confocal microscopy. **C:** PML entrapment of nucleocapsids in neurons in human DRG xenografts in SCID mice. *Upper panel:* Neural cell with large ring-like PML cage (green) that sequesters ORF23 protein (red) in infected human DRG xenograft. *Lower panel:* a large, ring-like PML cage that sequesters numerous VZV NCs in infected neural cells shown by PML-specific immunogold-labeling of ultrathin (80-nm) cryosection. **D:** ORF61 disruption of PML nuclear bodies in skin. *Upper panel:* Replication of pOka and ORF61 SIM mutant viruses in human skin xenografts in SCID mice; mean titer \pm SEM at 10 and 21 days postinfection. *, $p < 0.05$; ***, $p < 0.001$; vs pOka (two-way ANOVA). *Lower panel:* ORF61/PML NB association in pOka- or pOka-mSIM-N&C-infected cells shown as percentage of cells that did/did not have ORF61 co-localization with PML NBs; ***, $p < 0.0001$. **E.** Autophagosomes in a varicella lesion. A keratinocyte exhibited LC3B puncta characteristic of LC3B-II in autophagosomes in a VZV-infected cell identified by IE62 immunoreactivity. (A adapted from Eisfeld AJ, Yee MB, Erazo A, et al. Downregulation of class I major histocompatibility complex surface expression by varicella-zoster virus involves open reading frame 66 protein kinase-dependent and -independent mechanisms. *J Virol* 2007;81(17):9034–9049. genes, as shown by comparing VZV-infected and uninfected cells from the same culture.⁵⁶⁷ IE62 alone prevents TANK-binding kinase (TBK1)–mediated IRF3 function and IFN- β secretion through a novel mechanism in which IRF3 phosphorylation is blocked. This antiviral activity of IE62 is independent of its function as a transactivating protein. IFN- α triggers production of cell proteins that phosphorylate the alpha subunit of eukaryotic initiation factor 2 (eIF-2 α), which blocks translation. VZV can block eIF-2 α phosphorylation through an IE63-dependent process, preventing this IFN- α effect,^{7a} possibly as a redundant mechanism if IE62 interference with

IFN- β is incomplete. ORF47 kinase contributes to inhibition of IRF3 activation by altering its phosphorylation and blocking homodimer formation,⁶³⁴ and ORF61 degrades phosphorylated IRF3⁷¹⁹ in HEK293 cells; these cells do not support productive infection, however.

PROMYELOCYTIC LEUKEMIA PROTEIN NUCLEAR BODIES (PML-NBs).

PML-NBs, also known as ND10 bodies, restrict herpesvirus gene expression in newly infected cells and are upregulated by IFNs. Whereas HSV ICP0 degrades PML protein and

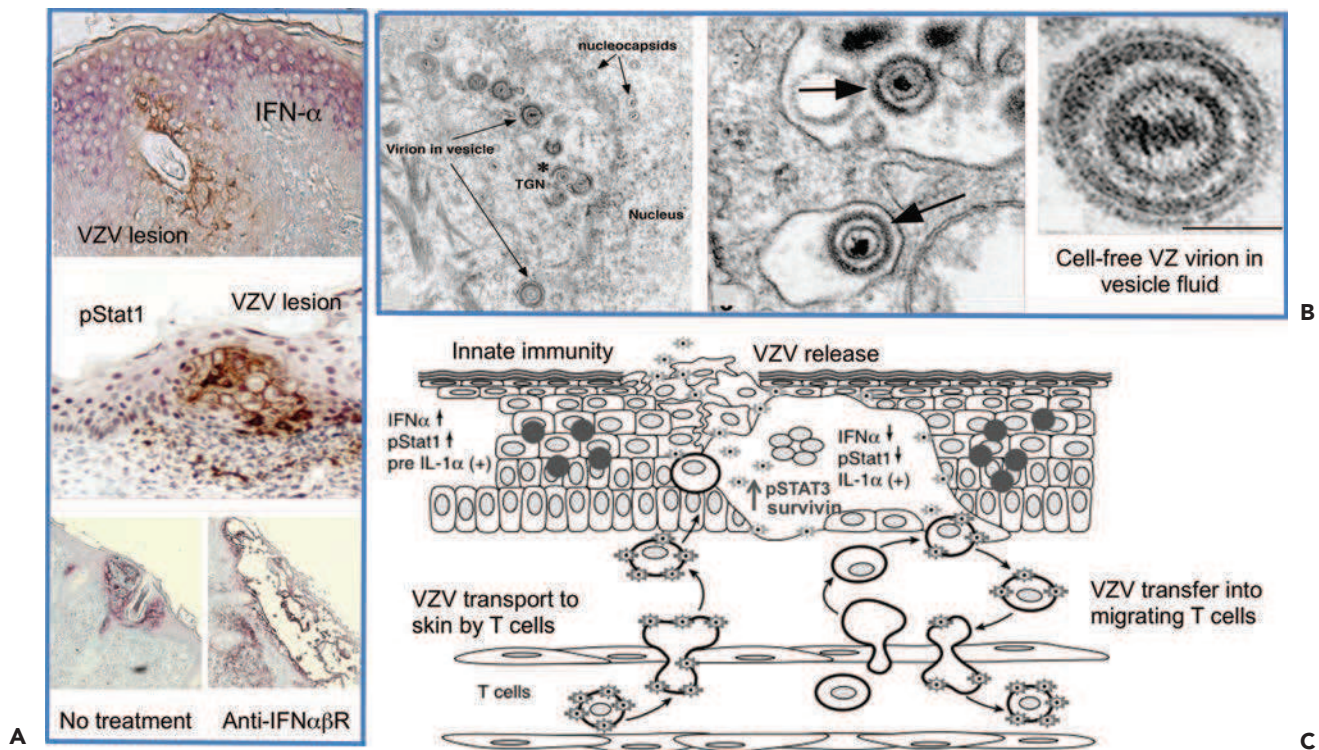

FIGURE 63.10. Varicella-zoster virus (VZV) infection of skin. Formation of epidermal lesions that penetrate the skin surfaces requires 10 to 21 days because of potent innate antiviral responses of epidermal cells. **A:** VZV lesions are formed by cell-to-cell spread overcoming the interferon barrier (IFN- α and pSTAT) in surrounding uninfected cells; interference with the innate IFN response by treatment of SCID mice with antibody against the IFN α/β receptor results in formation of large skin lesions. **B:** Electron micrograph of the suprabasal epidermis of a varicella skin lesion showing all stages of viral envelopment in infected keratinocytes. Unenveloped nucleocapsids are seen in the nucleus while nucleocapsids are being enveloped (*) by specialized cisternae of the TGN/transport vesicles (arrows), each containing a single enveloped virion (left panel). Accumulating cytokeratin filaments are visible in the cytoplasm of the keratinocytes (lower left of center panel). Keratinocytes of the suprabasal layers of the VZV-infected epidermis secrete intact virions to the extracellular space (arrows in right panel indicate two extracellular virions). A virion from a varicella vesicle is illustrated at high magnification and imaged in bright-field; note the spikes on the viral envelope, the complexity of the underlying tegument, and the apparent connections between the nucleocapsid and the tegument (scale bar = 100 nm) (right panel). **C:** Schema of skin infection during primary VZV infection. Activation of innate responses (IFN, pStat1, NF κ B) in uninfected cells is triggered by VZV replication. Within infected cells, VZV activates STAT3 and the antiapoptotic protein survivin. Uninfected T cells that traffic through sites of VZV lesion formation may amplify VZV viremia, and infected dendritic cells may transfer the virus to regional lymph nodes, enhancing T cell-mediated viremia. (A adapted from Ku CC, Zerboni L, Ito H, et al. Varicella-zoster virus transfer to skin by T cells and modulation of viral replication by epidermal cell interferon- α . *J Exp Med* 2004;200:917–925. STAT3 Activation and survivin induction by varicella zoster virus promotes viral replication and skin pathogenesis. *PNAS* 2012;109:600–605).

PML-NBs, VZV-infected cells do not exhibit PML degradation,³⁴⁷ although the architecture of PML-NBs is disrupted in VZV-infected cells *in vitro* and in human skin xenografts through an ORF61-mediated effect. Dispersal of PML-NBs depends on small ubiquitin-like modifier (SUMO)-interacting motifs (SIMs) in ORF61 (Fig. 63.9).⁶⁵⁴ In the absence of SIMs, ORF61 association with PML-NBs is reduced, most PML-NBs remain intact, and VZV skin infection is severely impaired. The IFN response in VZV-infected skin is associated with even higher numbers of PML-NBs in dermal and epidermal cells, and the ORF61 SUMO-binding capacity is necessary to counteract this intrinsic barrier. Furthermore, incomplete dispersal

of PML-NBs by VZV inhibits egress of VZ capsids from the infected-cell nucleus, impairing the synthesis of infectious virus progeny. This antiviral mechanism has biologic significance, since neurons and satellite cells in human DRG and skin cells infected with VZV *in vivo* contain large PML-NBs that sequester newly assembled nucleocapsids (Fig. 63.9).⁵²⁶ This function is mediated by the unique carboxy-terminus of PML IV, which interacts with the ORF23 capsid surface protein to trap capsids and inhibit VZV replication. PML-dependent sequestration of nucleocapsids appears to be a common cytoprotective function of these PML-NBs, in which aberrant proteins are sensed and aggregated in neuronal cell nuclei.

Modulation of Surface Expression of Cellular Proteins Involved in the Host Response

VZV downregulates expression of MHC class I proteins on the surface of infected fibroblasts and T cells, with these proteins retained in the Golgi compartment in virus-infected cells,¹ although the total amount and rate of synthesis of class I molecules is unchanged in VZV-infected cells. Most of this effect is mediated by ORF66 (Fig. 63.9).^{1,157} VZV also inhibits IFN- γ induction of MHC class II molecules on the infected cell surface,⁴ preventing recognition of infected cells by VZV-specific CD4 or CD8 T cells. Infection of mature dendritic cells with VZV results in downregulation of surface MHC class I, CD80, CD83, and CD86, and inhibits their ability to stimulate proliferation of allogeneic T cells.⁴⁴⁶ VZV also downregulates Fas expression on the surface of dendritic cells.²

Regulation of Apoptosis and Autophagy

VZV induces apoptosis with chromatin condensation and DNA fragmentation in Vero cells, B cells, T cells, and human fibroblasts, but not in primary human DRG neurons.⁵⁴⁴ Conversely, expression of IE63 in sensory neurons inhibits apoptosis induced by withdrawal of nerve growth factor.²⁶⁶ Caspase-8 transcripts are reduced, whereas two IRF gene transcripts (ADAR, MxA) are increased in VZV-infected T cells. In contrast, caspase-8 transcripts are not reduced in virus-infected fibroblasts or skin cells.²⁹⁴ VZV ORF66 expression inhibits apoptosis induced by VZV in T cells⁵⁵⁹ and is required for efficient growth in corneal epithelial cells, although interference with apoptosis is not the only ORF66 function required in these cells.¹⁵⁹ STAT3 activation by VZV results in upregulation of survivin, exerting a proviral effect by inhibiting apoptosis.⁵⁶⁸

Whereas HSV-1 ICP34.5 inhibits autophagy, VZV lacks an ICP34.5 homolog. VZV infection induces autophagy-associated proteins and formation of autophagosomes in cultured cells and in keratinocytes that express IE62 within varicella and zoster skin lesions (Fig. 63.9).^{66a,612} Autophagy appears to be preceded by ER stress and the unfolded protein response triggered by excessive glycoprotein synthesis, such as the abundant synthesis of gE in VZV-infected cells. These processes are associated with the inhibition of apoptosis.

PATHOGENESIS AND PATHOLOGY

In the usual course of VZV infection, the virus exhibits tropism for T cells, cutaneous epithelial cells, and cells of sensory nerve ganglia (Fig. 63.1). VZV can also infect other tissues when cell-associated viremia and viral replication are not controlled by intrinsic or adaptive host immune responses. Under these circumstances, disseminated infection may involve the lungs, liver, central nervous system (CNS), and many other organs.⁴⁵² Pathologic changes in these tissues may be caused by replicating virus and, in some instances, by inflammatory or immune-mediated injury. VZV and simian varicella virus (SVV) pathogenesis have similarities consistent with the genetic relatedness of these two primate *Varicelloviruses*.^{148,215,216,217,275,314,375,384,285,386,387,388,389} The clinical manifestations of varicella and zoster that are associated with events in VZV pathogenesis and the pathologic changes associated with VZV syndromes are described in the Clinical Features section.

Entry into the Host

Primary VZV infection (varicella) is presumed to be initiated by inhalation of respiratory droplets containing virus particles or by inoculation of mucosal epithelium with infectious vesicular fluid from an individual with varicella or zoster. The potential for aerosol transmission is suggested by epidemiologic reports, and VZV DNA is detected in air samples from rooms occupied by patients with varicella or disseminated zoster.⁵⁵⁵

Site of Primary Replication and Viral Spread

Initial VZV replication is likely to occur in respiratory mucosal epithelial cells (Fig. 63.1). Following an incubation period of 10 to 21 days, primary VZV infection results in varicella. Although T-cell tropism appears to be a necessary component of primary VZV infection, the site and mechanisms whereby T cells become infected cannot be defined in the human host. Tonsillar T cells—especially those that are activated and express skin homing markers, predominantly memory CD4 T cells—are most permissive for VZV infection, suggesting that spread of VZV from infected mucosal epithelial cells to these T cells initiates cell-associated viremia.³⁴³ Respiratory mucosal epithelial cells line tonsil crypts, penetrating deep into tonsillar tissues that contain many T cells, and migrating T cells traffic across this epithelial cell layer into tonsils. Dendritic cells are also present in mucosal epithelium and may transfer the virus to T cells in regional lymph nodes.³ Viremia may be amplified during infection as T cells traffic through infected skin and visceral organs, such as the liver. VZV is detected in PBMCs from individuals just before or after the onset of the rash.^{28,483,558,642} Infected cells are present at low frequency (0.01% to 0.001% of PBMC)³³⁶ and are usually cleared within 24 to 72 hours after the appearance of the rash. SVV also causes a robust cell-associated viremia that precedes the cutaneous exanthem,^{90,215,416,683} whereas VZV produces a limited viremic phase in guinea pigs.^{378,453}

VZV proteins that are required for or contribute to T-cell tropism *in vivo* as identified in T cell-containing xenografts in the SCID mouse model include gI, ORFs 66, 35, and 47 as well as residues 51 to 187 in the unique gE N-terminus, the residues required for gE binding to gI and, to a lesser extent, the gE AYRV TGN targeting motif (Table 63.1). VZV T cell-associated viremia is likely to be facilitated by downregulation of MHC class I protein, inhibition of apoptosis by ORF66, and by STAT3 activation with survivin induction.

Experiments in the SCID mouse model indicate that VZV is transported by infected human T cells to skin xenografts soon after they enter the circulation. However, the spread of VZV in skin is countered by a potent innate immune barrier resulting from constitutive IFN expression and upregulation of the cellular transactivators STAT1 and NF- κ B in epidermal cells, along with the high frequency of PML nuclear bodies in basement membrane cells of the dermis.^{293,342,344,654} (Fig. 63.10). Blocking IFN responses accelerates VZV infection in skin dramatically. The long interval between VZV exposure and the appearance of varicella skin lesions appears to reflect the time required for VZV to overcome these robust intrinsic obstacles.

Skin Tropism

During varicella, skin cells become major sites of virus replication (Fig. 63.10). The virus may gain access to cutaneous

epithelial cells by migration of intact, infected T cells out of the capillaries into cutaneous tissue, followed by release of virions. Alternatively, infectious virus may move from T cells into capillary endothelial cells. Inclusions and VZV proteins have been observed in capillary endothelial cells and adjacent epithelial cells in VZV lesions.⁴⁶⁷ Cells lining the lymphatics of the superficial dermis become dilated and contain intranuclear inclusions, suggesting VZV infection. Cutaneous dendritic cells and Langerhans cells are susceptible to VZV and may contribute to local replication and spread.³

Classic studies of varicella lesions by Tyzzer in 1906⁶²⁸ showed that the earliest changes consist of vasculitis involving the endothelium of small blood vessels, whereas the emergence of enlarged, multinucleated epithelial cells with intranuclear eosinophilic inclusions is typical of the second, maculopapular stage of the lesions. Progressive degeneration of epithelial cells, coalescence of fluid-filled vacuoles between cells, and destruction of the basement membrane occur as maculopapular lesions evolve into vesicles (Fig. 63.1).

VZ virions are abundant in keratinocytes and in vesicular fluid (Fig. 63.10). In skin biopsy specimens, early lesions show IE63 in keratinocytes; later, gE, gB, and IE63 are detected in keratinocytes, sebocytes, Langerhans cells, dermal dendrocytes, monocyte-macrophages and endothelial cells. Viral proteins are also expressed in dermal nerves and in perineural type I dendrocytes.¹⁵ Infiltration of the involved skin sites by inflammatory cells is minimal in the early vesicular phase, whereas later, upregulation of adhesion molecules on capillary endothelial cells is associated with extensive mononuclear cell migration into the skin lesions.²⁶³ In the final phase, cutaneous lesions progress to ulceration and necrosis.

VZV proteins that are required for or contribute to skin tropism, as assessed in skin xenografts in the SCID mouse model, include ORFs 10, 11, 31, 35, 47, 61, and 66; gI and particular residues in gI; and specific motifs within gE (Table 63.1). The passage of the Oka virus in tissue culture alters its capacity to infect skin, and analysis using vaccine/parental Oka chimeric viruses indicates that multiple VZV genes are involved in skin tropism.⁷⁰⁶

Like VZV, SVV produces a cutaneous rash within 10 to 12 days after close contact with infected animals or following intratracheal inoculation.^{140,384,386,416}

Release from the Host

Many cell-free VZV virions are released into vesicular fluid of skin lesions, which facilitates transmission by direct contact. VZV differs from other human herpesviruses in that infectious virus can be released into respiratory secretions and spread to susceptible persons by airborne transmission.²³⁵ Viral DNA can be detected by PCR in specimens obtained from respiratory sites in the late stage of the incubation period and during the first few days of rash.^{27,558} VZV DNA can also be detected in saliva during and after zoster, but it is not known whether infectious particles are present.^{409,459}

Virulence

Naturally circulating strains of VZV do not exhibit intrinsic differences in virulence, as judged by the clinical consequences of primary VZV infection. Nonetheless, circulating strains of VZV do differ in their genome sequences, allowing assignment to clades (Fig. 63.4). The enhanced growth of the naturally

occurring VZV-MSP variant in skin xenografts in SCID mice suggests that a single amino acid change in gE can alter pathogenesis.⁵⁴⁷ VZV TK-negative viruses have been isolated from patients given prolonged acyclovir therapy, but altered pathogenicity has not been described.⁶⁷⁷ VZV isolates from three patients with encephalitis did not have distinctive genetic characteristics.⁵⁶ A study of Oka vaccine viruses isolated from skin revealed the same DNA sequence (a clonal isolate), whereas virus isolated from lungs contained mixed DNA sequences but with no identifiable changes related to tropism.⁵¹⁵ In addition, viruses isolated from skin lesions after vaccination have been found to have *ORF62* genes that encode amino acids characteristic of the parent strain rather than the substitutions identified in the vaccine, suggesting that a natural selection for these residues occurs during replication in the human host.^{513a} As demonstrated in the SCID mouse model, many VZV genes and promoter regulatory elements contribute to VZV cell tropism and virulence (Table 63.1).

Latency

VZV gains access to sensory ganglia, either hematogenously or by centripetal neural transport from mucocutaneous lesions during primary infection, where it establishes latency.^{155,593} The importance of cell-associated viremia in the delivery of the varicelloviruses to sensory ganglia is supported by clinical reports of VZV detection at these sites before rash has appeared and in nonhuman primates infected with SVV.^{387,388,389} Alphaherpesvirus latency is characterized by the presence of viral DNA in ganglionic neurons (Fig. 63.11), limited viral gene transcription, and the potential for reactivation. VZV becomes latent in neurons in cranial nerve, dorsal root, and autonomic ganglia along the human neuraxis.^{179,203,204,276,311,348,392,393,617,652} Based on autopsy studies, the prevalence of VZV latency in the population varies from 63% to 100%^{111,274,367,392,502}; in the largest study, VZV DNA was found in 94% of 414 trigeminal ganglia.²⁷⁹ Use of precise laser capture microdissection and PCR revealed VZV DNA in 4.1% of neurons and in less than 0.1% of satellite cells.⁶⁵²

Latent VZV DNA assumes a circular or concatameric form⁸⁸ and is present at a frequency of 2 to 9 genome copies in 1% to 7% of neurons, which corresponds to a virus burden of 30 to 3,500 copies per 100 ng of ganglionic DNA.^{111,267,300,311,348,360,502,652} The wide range of genome copy number in latently infected ganglia may reflect the extent of primary VZV infection, since both the extent of cell-associated viremia and the number of cutaneous lesions is highly variable.^{126,394,536} Episodes of VZV reactivation or possibly reinfection may also increase the virus burden in latently infected ganglia.

VZV gene expression is highly restricted during latency. *In situ* hybridization detected transcripts mapping to *ORFs* 4, 18, 21, 29, 40, 62, and 63 but not to *ORFs* 28 or 61 in human trigeminal ganglia.³⁰⁹ Transcripts mapping to *ORFs* 21, 29, 62, 63, and 66, but not *ORFs* 4, 10, 40, 51, or 61, were detected in latently infected trigeminal ganglia by PCR amplification of cDNA libraries^{104,112} and confirmed by sequence analysis of the 3'-polyadenylated termini.^{104,105,106,111,112,410} Most recently, multiplex PCR technology (GeXP) was applied to mRNA extracted from 26 latently infected trigeminal ganglia and one control trigeminal ganglion negative for VZV DNA from 14 individuals, 16 to 84 years of age, within 24 hours after death; the

FIGURE 63.11. Varicella-zoster virus infection of human sensory ganglia. **A:** Detection of VZV DNA by *in situ* hybridization in the nucleus of a neuron in sensory ganglion section obtained postmortem from a patient without signs of zoster. **B:** Immunohistochemical detection of IE63 protein in neuron cytoplasm (arrow) in a thoracic ganglion section using rabbit anti-VZV ORF63. **C:** Immunohistochemical detection of IE63 protein in dorsal root ganglion sequential sections using rabbit preimmune IgG antibody (upper panel) and matched high-titer rabbit anti-IE63 IgG at magnifications $\times 100$ (center panel) and $\times 200$ (lower panel); white arrows indicate DAB-positive cells; black arrows indicate fibrous bands as a reference point. **D:** Immunohistochemical detection of IE4, IE62, and IE63 in sensory ganglion sections from a patient with zoster at time of death using purified anti-VZV protein rabbit antibodies and AP-conjugated goat anti-rabbit Ig secondary antibody. **E:** Immunohistochemical detection of CXCL10 in dorsal root ganglia from a patient with zoster rash at time of death. The ganglion innervating the site of the rash contained CXCL10-positive neurons (arrow) and infiltrating cells (arrowhead, upper panel). Lower panel shows isotype control staining of the consecutive section. **F:** Immunofluorescence detection of CXCR3 (red) and S100b (green) and counterstained with DAPI (4',6-diamidino-2-phenylindole) (blue) in the same ganglia as in **E**. Nonneuronal CXCR3-positive cells were observed throughout the reactivated lumbar DRG (arrows), with some CXCR3-positive cells juxtaposed to neurons (boxed region, upper panel); higher-power magnification of the inset box (lower panel). presence of *ORF 4*, *29*, *40*, *62*, and *63* transcripts was confirmed and *ORF 11*, *41*, *43*, *57*, and *68* transcripts were detected.⁴⁵⁵ The 10 VZV ORFs transcribed during latency represented putative IE, early, and late genes. The detection of transcripts corresponding to all stages of the VZV life cycle contrasts with findings in HSV latency, in which only a single HSV latency-associated transcript (LAT) has been identified thus far. Further information on the extent of HSV gene transcription awaits the use of GeXP to study ganglia latently infected with HSV.

By quantitative analysis, *ORF63* is the most abundant and prevalent VZV transcript.^{111,455} *ORF63* transcripts in individual ganglia vary more than 2,000-fold, ranging from 1 to 2,785 copies per 10,000 copies of GAPdH transcript,¹¹¹ and *ORF63* transcripts were detected in 17 of 28 ganglia, with as many as

29,000 copies per 1 μ g of input mRNA. The consistent detection of *ORF63* transcripts in high abundance is not understood.

Deep sequencing of RNA extracted from human trigeminal ganglia positive for VZV and HSV-1 DNA revealed microRNAs (miRNAs), the small noncoding RNA molecules that can alter transcript stability and translation, mapping to the HSV-1 genome but not the VZV genome.⁶³⁰ Since HSV-1 miRNAs map to the LAT locus and VZV has no similar region, the lack of VZV miRNA may reflect a basic difference in the mechanism by which these neurotropic alphaherpesviruses maintain latency.

Chromatin immunoprecipitation (ChIP) assays followed by PCR have been used to elucidate the epigenetic state of VZV genomes.¹⁸⁸ Like HSV-1 DNA, histones are associated with VZV DNA at all stages of the viral life cycle, but the histone

composition differs during productive infection and latency. Acetylated histone H3K9(Ac), indicative of a euchromatic (transcriptionally active) state, is associated with the *ORF62* and *ORF63* promoters during both latent infection in human ganglia and lytic infection of human melanoma (MeWo) cells. Neither *ORF14* (glycoprotein C) nor *ORF36* (thymidine kinase) is transcribed or associated with H3K9(Ac) during latent infection. Chromatin remodeling appears to contribute to the restricted pattern of latent VZV gene transcription. An IE63 interaction with human anti-silencing function 1 protein interferes with its capacity to bind histones h3.1 and h3.3.⁸

VZV protein expression in latently infected ganglia has been assessed using antibodies that detect viral proteins in cultured cells to stain ganglion tissue sections. IE63 was first identified in rare ganglion neurons by Mahalingam et al.³⁹¹ (Fig. 63.11). Detection of IE62^{274,617} IE63,³⁸¹ ORF66¹⁰⁶ and proteins encoded by *ORFs* 4, 21, and 29²¹⁹ during latency has also been described. Some of these reports identify IE62 and IE63 as restricted to the cytoplasm of neurons, in contrast to their prominent nuclear localization during lytic infection. This pattern has been proposed to indicate a mechanism by which latency is maintained; IE63 and other VZV proteins have been referred to as VZV latency-associated proteins. However, not only does the frequency of neurons reported to express VZV proteins vary substantially among these studies, ranging from very few to more than 30%, but also the frequency of neurons expressing VZV proteins in some reports exceeds the frequency of neurons harboring VZV genomes. Furthermore, viral proteins, such as IE4, are detected but their transcripts are not. These discrepancies suggest technical problems with analysis of autopsy specimens using antibody reagents that are specific for VZV proteins in cultured cells.

It is now recognized that ascites-derived monoclonal antibodies and rabbit antisera may contain endogenous antibodies to human blood group A determinants. Ascites-derived monoclonal antibodies to VZV IE62, gE, and ORF40 capsid protein produce a cytoplasmic Golgi-like pattern of staining in neurons of blood group A subjects (~30% to 40% prevalence)⁷¹²; isotype reagents do not serve as a control for this reactivity. The apparent expression of VZV proteins in neurons at high frequency is no longer detected if endogenous anti-A antibodies are eliminated by deriving monoclonal antibodies in tissue culture or adsorbing antisera with erythrocytes from blood group A individuals.⁷¹² IE63 expression was rare when ganglion sections were stained with anti-IE63 rabbit antiserum and with preimmune serum to control for blood group A reactivity,⁷¹⁰ which confirmed two earlier reports^{309,391} (Fig. 63.11). The presence of neuronal cell pigments is another confounding factor in evaluating viral protein expression by immunohistochemistry, and IE62 has an epitope that cross-reacts with brain-derived neurotropic protein found in the neuron cytoplasm.²³⁸ Together, the evidence points to the presence of VZV proteins in only a few neurons in sensory ganglia from latently infected individuals with no signs of zoster at the time of death if blood group A and other variables are eliminated in the staining conditions. Thus, VZV protein expression is not a characteristic of VZV latency, with detection in rare neurons probably reflecting early or abortive reactivation.

Investigations of VZV neurotropism *in vivo* have used the SCID mouse model, in which human DRG are xenografted under the mouse kidney capsule and infected with VZV. In this

model, a limited lytic infection of DRG occurs in the first 14 days (Fig. 63.12). VZV virions are detected in neurons and satellite cells, and infectious virus is produced.^{527,707,709} By 1 month, no infectious virus is released from cells, virion assembly ceases, and VZV genome copy numbers are reduced. ORF63, and less consistently ORF62, continue to be transcribed but gB expression is silenced. Viral genomes remain in DRG for at least 8 months. This transition from lytic to persistent infection indicates that VZV latency can be established in human neurons in the absence of adaptive immunity, since SCID mice do not generate antigen-specific T cell or humoral immunity.

Like VZV, SVV establishes latent infection in ganglionic neurons at multiple levels of the neuraxis, but not in lung or liver.^{314,386} VZV neurotropism has also been investigated in rodent and guinea pig models.^{81,86,310,378,543} Inoculation of cotton rats by injections adjacent to the spine and sensory ganglia with VZV mutants showed that *ORFs* 1, 2, 10, 13, 14, 17, 21, 32, 47, 57, 61, 66, and 67 were dispensable for VZV DNA persistence in ganglion tissues whereas *ORF* 4, 63, and 66 mutants were impaired.

Reactivation

The factors that trigger VZV reactivation from latency in infected neurons are unknown. Three possible outcomes of reactivation are: abortive infection restricted to the ganglia; transport of virus particles to skin but with lesion formation blocked by innate and adaptive immunity; and cutaneous lesion formation, manifest as zoster (see Clinical Features). Zoster is a vesicular rash typically confined to a dermatomal distribution²⁶⁹ and differs from the patchy distribution of cutaneous HSV vesicles (Fig. 63.13). The histopathology and viral protein expression in zoster and varicella lesions are similar^{449,467} (Fig. 63.11); viral proteins and inclusion bodies are observed within the small nerves in the dermis.¹⁵ Unlike HSV, infectious VZV has only been recovered in human ganglia from patients with active zoster.^{429,505}

The pathology of VZV reactivation in ganglia is characterized by inflammation and hemorrhagic necrosis with associated neuritis, localized leptomeningitis, unilateral segmental myelitis, and degeneration of related motor and sensory roots.^{127,253} Demyelination is seen in areas with mononuclear cell infiltration and microglial proliferation. Intranuclear inclusions, viral DNA and proteins (Fig. 63.11), and viral particles are found in acutely infected ganglia.^{78,160,197,205,380} VZV-infected cells have been detected in subependymal microvessels in fatal zoster cases. VZV reactivation may be followed by vasculopathy affecting large and small vessels with resultant cortical and subcortical infarction and ovoid mixed necrotic and demyelinating lesions, particularly in deep white matter and periventricular ependyma.³³³ VZV reactivation has been demonstrated in ganglia in the absence of cutaneous rash.¹³⁹

The lytic phase of VZV infection of DRG xenografts in SCID mice can be considered a model of events that occur during VZV reactivation⁵²⁷ (Fig. 63.14). Both neurons and satellite cells are productively infected.^{707,709} Importantly, VZV induces cell-cell fusion between neurons and satellite cells and spread from satellite cells to adjacent uninfected satellite cells. Infection of these cells surrounding neuronal cell bodies facilitates access of the virus to other neuronal cell bodies. Similar cell-cell fusion has been observed in ganglia obtained at autopsy from patients with zoster.¹⁶⁰ During VZV

FIGURE 63.12. Varicella-zoster virus (VZV) infection of dorsal root ganglia xenografts in the SCID mouse model. **A:** DRG xenografts retain organotypic features of normal human ganglia (H&E stain; $\times 100$). **B:** DRG xenograft 14 days after infection; *arrow* indicates cytopathology in neurons (H&E stain; $\times 200$). **C:** DRG xenograft 14 days after infection stained with rabbit polyclonal antibody to VZV IE63 (brown, DAB signal) and counterstained with hematoxylin ($\times 200$). **D:** DRG xenograft 56 days after VZV infection, showing no evidence of productive infection (H&E stain; $\times 200$). **E:** VZV genome copy numbers in VZV-infected DRG xenografts evaluated by quantitative real-time DNA PCR at 14, 28, and 56 days postinfection using a probe to ORF62. **F:** VZV gene transcripts evaluated by quantitative real-time RNA PCR at 56 days postinfection using probes to ORF31 (gB), ORF62, and ORF63 mRNAs. **G:** Immunoblot (*upper panel*) of DRG extracts using human polyclonal anti-VZV antibody, primarily reactive against VZV gE in VZV-infected DRG at days 14 and 56 postinfection; immunoblot (*lower panel*) of DRG extracts using human polyclonal anti-VZV antibody and rabbit polyclonal antibody to IE63 in DRG at 70 days after infection with VZV or the VZV gI deletion mutant Δ gI, indicating cessation of protein expression in VZV- compared to Δ gI-infected DRG, which exhibit prolonged active infection. (Adapted from Zerboni L, Ku C-C, Jones CD, et al. Varicella-zoster virus infection of human dorsal root ganglia in vivo. *Proc Natl Acad Sci U S A* 2005;102:6490–6495; and Zerboni L, Berarducci B, Rajamani J, et al. reactivation, amplification by spread to other neuronal cell bodies within the ganglia presumably allows delivery of virus particles from many neurons along axons to the skin in the affected dermatome. VZV damage to both satellite cells and neurons in the ganglia helps to account for the neurologic consequences that are rare during HSV reactivation.

SVV also reactivates in a dermatomal distribution either spontaneously or after drug- or radiation-induced immunosuppression.^{387,388,389} SVV glycoproteins are detected in zoster skin lesions, lungs, and multiple ganglia of most immunosuppressed monkeys, but not in control animals.³⁸⁸ Of interest, subclinical SVV reactivation after irradiation of rhesus macaques latently infected with SVV resulted in disseminated varicella in another irradiated SVV-seronegative monkey in the same colony.³³⁵

Postherpetic Neuralgia (PHN)

PHN is common after VZV reactivation (see Clinical Features). Two nonmutually exclusive theories to explain this pain are: an

altered excitability of ganglionic or even spinal cord neurons; and the presence of persistent or low-grade productive virus infection in ganglia. Analysis of ganglia from a case of PHN of 2.5 months' duration revealed diffuse and focal infiltration by chronic inflammatory cells⁵⁷⁷; collections of lymphocytes were prominent in ganglia from a patient with PHN of two years' duration⁶⁵⁹ (Fig. 63.13). Evidence that PHN may be due to low-level ganglionitis associated with prolonged viral infection has come from the detection of VZV DNA and proteins in PBMCs of patients with PHN.^{132,390,632} While antiviral therapy is not recommended for PHN, the favorable response of some patients to antiviral treatment supports the possibility that chronic ganglionitis may contribute to PHN.^{200,616}

Reinfection

Reinfection with VZV appears to be rare based on clinical criteria. Second episodes of varicella have been documented,¹⁹⁵ but confirmation of true reinfection with VZV as opposed to incorrect diagnosis of a previous vesicular rash is difficult. In

FIGURE 63.13. Characteristics of vesicular rash produced by varicella-zoster virus (VZV) versus herpes simplex virus reactivation and of ganglionitis associated with VZV reactivation and postherpetic neuralgia. **A:** Extensive dermatomal lesions characteristically produced by VZV compared to the patchy skin lesions produced by HSV. **B:** Sections of dorsal root ganglia (H&E staining) from two patients with PHN lasting 2.5 months (*right panel*) and 2 years (*left panel*) reveals diffuse and focal infiltration by chronic inflammatory cells; *arrow in right panel* points to a prominent collection of lymphocytes. (Adapted from Watson CPN, Deck JH, Morshead C, et al. Postherpetic neuralgia: further post-mortem studies of cases with and without pain. *Pain* 1991;44:105–117; and Smith FP. Pathological studies of spinal nerve ganglia in relation to intractable intercostal pain. *Surg Neurol* 1978;10:50–53.)

a cohort of adults who developed varicella despite a previous episode, none had VZV antibodies in sera obtained before the acute illness, suggesting that the earlier exanthem was not caused by VZV.⁶⁴⁵ Most immunocompromised patients who have had prior VZV infection and who develop signs suggestive of a second episode of varicella likely have generalized, atypical reactivation without dermatomal involvement rather than reinfection. Immunologic evidence of reinfection in healthy and immunocompromised patients is indirect; infection may not be necessary to trigger the increases in antibody and cellular immunity to VZV that occur when immune subjects have close contact with an infected person. Antigen presentation with enhancement of adaptive immunity can occur without any viral replication, as observed when immune individuals receive inactivated varicella vaccine. Since vaccinated individuals can develop zoster due to wild-type VZV, subclinical reinfection can occur despite vaccine-induced immunity.¹⁸⁹

Immune Response

IMMUNE CONTROL OF PRIMARY VZV INFECTION.

In addition to local antiviral responses mediated by epidermal cells (Fig. 63.10), innate cell-mediated responses are likely to be important in the initial control of VZV infection. Natural

killer (NK) cells from nonimmune individuals lyse VZV-infected fibroblasts²⁸² and also produce granulysin, which has antiviral activity.²⁴⁹ IFN- α is detected in serum at the onset of varicella²⁰ and may limit early viral replication, as suggested by its clinical efficacy in modifying the severity of varicella in immunocompromised children and by the association of more severe varicella in adults with reduced serum IFN- α .^{22,646} The innate response to primary VZV infection also appears to involve invariant natural killer T cells (iNKT) and antigen presentation to these unusual T cells by CD1, a nonclassical MHC class I molecule, as suggested by the disseminated infection after administration of varicella vaccine virus in a child with deficient iNKT cells and CD1 expression but no other evidence of a primary immunodeficiency disorder.³⁷

The initial stages of primary VZV infection before and in the first few days of rash evoke little or no adaptive immunity, as measured by antibody production or assessment of T cells that recognize VZV antigens. Nevertheless, although the virus can evade induction of and recognition by CD4 and CD8 T cells transiently, replication is well contained when VZV-specific immunity is induced¹⁷ (Fig. 63.15). Robust cellular immunity is elicited even when the varicella rash consists of fewer than 10 lesions. Unless the host is compromised, this pattern of

FIGURE 63.14. Polykaryon formation in acutely infected DRG. A–C. Immunofluorescence analysis of acutely infected DRG. Cryosections of VZV-infected DRG were stained with mouse monoclonal anti-NCAM antibody (**A–C**; green), rabbit polyclonal anti-synaptophysin antibody (**A**; red), rabbit polyclonal anti-IE62 antibody (**B, C**; red) and Hoechst stain (blue). Texas red-labeled goat anti-rabbit or FITC-labeled goat anti-mouse antibodies were used for secondary detection. Satellite cells (s) and neurons (N) are marked with letters; *asterisks* (*) indicate nuclei of satellite cells located within a putative polykaryon. *Arrowheads* point to cell boundaries detected by NCAM staining (green). Scale bars = 10 μ m. **D–G.** EM analysis of acutely infected DRG. *Arrowheads* point to the cell membrane surrounding satellite cells (s) or the neuron cell body (N) or a polykaryon (**F, G**). Black boxes in **D** and **F** indicate the area shown at higher magnification in **E** and **G**, respectively. Note that despite the normal morphology of the mitochondria, the ER and the nuclear envelope in the polykaryon (**F, G**), no cell membranes between the nuclei of the polykaryon are detected. (Adapted from Reichelt M, Zerboni L, Arvin AM. Mechanisms of varicella-zoster virus neuropathogenesis in human dorsal root ganglia. *J Virol* 2008;82(8):3971–3983).

FIGURE 63.15. The immune response to varicella-zoster virus (VZV) infection. Upper panel: Schematic of VZV T cell immunity. Varicella is the primary infection caused by VZV, and its resolution is associated with the induction of VZV-specific memory T cells (blue line); varicella vaccine also induces memory T cells. Memory immunity to VZV may be boosted periodically by exposure to varicella or silent reactivation from latency (red peaks). VZV-specific memory T cells decline with age. The decline below a threshold (dashed green line) correlates with an increased risk of zoster. The occurrence of zoster, in turn, is associated with an increase in VZV-specific T cells. Administration of zoster vaccine to older persons may prevent VZV-specific T cells from dropping below the threshold for zoster occurrence (dashed blue line). (From Arvin A. Aging, immunity, and the varicella-zoster virus. *N Engl J Med* 2005;352:2266–2267, with permission.) **Lower panel:** Effects of zoster vaccination. **A:** Reduction of zoster. **B:** Reduction of postherpetic neuralgia. **C:** VZV-specific memory T cells in healthy adults given high-potency live attenuated VZV vaccine or placebo. (Adapted from Oxman MN, Levin MJ, Johnson GR, et al. Shingles Prevention Study Group. A vaccine to prevent herpes zoster and postherpetic neuralgia in older adults. *N Engl J Med* 2005;352:2271–2284; and Weinberg A, Levin MJ. VZV T cell-mediated immunity. *Curr Top Microbiol Immunol* 2010;342:341–357).

virus–host interaction initially favors the virus because cutaneous viral replication allows VZV transmission to other susceptible individuals, while the host is favored thereafter through the protection from illness on subsequent exposures afforded by memory B and T cells that recognize VZV antigens. Disease that could be initiated by VZV reactivation is also blocked as long as VZV-specific memory T cells are maintained in sufficient numbers.⁶⁶⁹

Primary VZV infection induces the production of IgG, IgM and IgA antibodies directed against many viral proteins.^{17,137,196} Antibodies can be detected in low concentrations in some individuals at the onset of the varicella rash and are usually present within 3 days. Antibodies to VZV proteins neutralize VZV replication, either directly or with complement, and also function in antibody-mediated cellular cytotoxicity.^{250,305} However, the humoral immune response appears to have little role in controlling primary VZV infection, since children with agammaglobulinemia have uncomplicated varicella. Among healthy children, the early detection of

high levels of circulating VZV-specific IgG or IgM antibodies does not predict disease severity. Moreover, children with T-cell immunodeficiencies may develop fulminant varicella, despite VZV antibody responses.²⁰

VZV antibodies administered passively after the appearance of varicella rash have no effect on disease progression. If present at or shortly after an exposure to VZV, passively acquired virus-specific antibodies can modulate or even prevent VZV infection of a susceptible individual.^{536,704} Transplacentally acquired IgG antibodies to VZV also protect infants from varicella or modify its severity. VZV-specific antibodies interfere with the initial phases of VZV replication *in vivo*, as shown by the reduced varicella attack rate in individuals given VZV immunoglobulin prophylaxis shortly after exposure.⁷⁰⁴ Passive antibodies may limit replication at initial sites, e.g., mucosal epithelium or lymphoid tissue, or may block or diminish cell-associated viremia or the early phase of VZV infection of epidermal cells. Anti-gH antibodies have neutralizing activity and may be important for this effect, as suggested by the restricted

skin infection in SCID mice given anti-gH antibody at the time of VZV inoculation.⁶³⁹

The critical role of VZV-specific cell-mediated immunity in controlling primary VZV infection is supported by correlations between the induction of virus-specific T cells and disease outcome.¹⁷ Cellular immunity appears to be important for terminating viremia and limiting virus replication at localized cutaneous sites. Healthy children who had T cells that recognized VZV antigens within 24 to 72 hours experienced milder varicella.²⁰ T-cell proliferation in response to VZV antigen is accompanied by the production of many cytokines, including IL-2 and IFN- γ , which amplify the initial antiviral response.²⁹⁰ Conversely, lymphopenia and failure to develop VZV-specific T-cell proliferation in immunocompromised children correlates with persistent viremia and risk of visceral dissemination.²⁰ Children with immunosuppression due to underlying diseases or interventions or those with primary cellular immunodeficiency diseases experienced progressive and often fatal varicella before the availability of antiviral drugs.⁴⁵² A similar pattern of acquisition of cell-mediated immunity and resolution of viremia and rash is observed in SVV infection; SVV-specific CD4 and CD8 T cells reach peak levels by 14 days.^{384,417}

MEMORY IMMUNITY.

Memory immunity to VZV is required to prevent symptomatic reinfection with exogenous virus and to prevent symptomatic VZV reactivations. The extent to which memory immunity contributes to the preservation of viral latency in neurons is not known. IgG antibodies that bind to viral glycoproteins and many other VZV polypeptides¹³⁷ and VZV-specific IgA antibodies are maintained, likely functioning as the first line of defense against reinfection.

Cell-mediated immunity to VZV proteins persists for years in the immunocompetent host. VZV-specific T cells respond to gB, gC, gE, gH, gI and the immediate early proteins IE62 and IE63.^{17,175,252} Healthy VZV-immune adults have circulating T cells that recognize an average of 7 of 10 IE62 peptides and 6 of 10 gE peptides.⁴³ Such individuals also have T cells that exhibit class I and class II MHC-restricted lysis of target cells expressing VZV antigens.^{134,570} Cytotoxic T lymphocytes (CTL) that recognize IE62 protein or gE are present at equivalent precursor frequencies in both the CD4⁺ and CD8⁺ memory T-cell populations.²⁶ VZV gC, gI, ORF4 protein, and ORF10 protein are also CTL targets.^{17,25} VZV-specific memory T cells circulate at low frequencies of about 5 per 100,000 PBMCs in immune adults,⁶⁶⁹ and memory CD4⁺ and CD8⁺ CTLs specific for individual VZV proteins circulate at frequencies of about 1 per 150,000 PBMCs. Intracellular cytokine detection assays showed that the mean percentage of VZV-specific CD4⁺ T cells based on IFN- γ or TNF- α production was about 0.12%.³⁰ Immune subjects also have persistent delayed-type hypersensitivity (DTH) responses to VZV skin test antigens.

Mechanisms by which memory immunity to VZV is maintained may include exposure to VZV through close contact with an infected person, since enhanced VZV T-cell proliferation, DTH, and VZV IgG antibodies often follow such contacts,²¹ and endogenous re-exposure to VZV antigens by subclinical reactivations. That endogenous re-exposures help to maintain VZV-specific T-cell responses is consistent with VZV-specific T-cell enhancement in older individuals given VZV vaccine.³⁶¹ Repeated antigenic stimulation may also result

if subclinical VZV reactivations lead to viral transfer to skin or mucosal sites of replication without progressing to zoster. This possibility is supported by the recovery of cell-mediated immunity to VZV in bone marrow transplant recipients who had no clinical episodes of zoster but had subclinical reactivations detectable by PCR.⁶⁸⁰ It is not known whether conditions necessary for CD4 and CD8 T-cell recognition of neurons harboring VZV are present during latency; if so, VZV immunity may be maintained by intermittent local expression of viral proteins during abortive reactivations. However, viral peptides can only be detected by T cells when present in MHC complexes, and class I MHC requires IFN- γ exposure for upregulation on neurons. Attempts to analyze local T-cell responses during latency have been hampered by the lack of a marker for cells harboring VZV genomes because VZV has no LAT region and viral proteins are rarely expressed.^{391,710,712}

IMMUNITY AND REACTIVATION.

T cells are present in ganglia obtained postmortem from latently infected individuals, but the extent to which VZV-specific T cells provide surveillance for early stages of reactivation in ganglionic neurons is unknown. Diminished T-cell responses to VZV antigens in older and immunocompromised individuals correlate with enhanced susceptibility to zoster,^{17,359,361} indicating the significant impact of waning immunity on the probability of symptomatic disease upon virus reactivation. The restoration of VZV T-cell immunity and the reduced risk of zoster in immunocompromised and elderly individuals given VZV vaccines has confirmed this hypothesis⁴⁸² (Fig. 63.15). Age-related immunosenescence is also associated with a decrease in DTH responses to VZV antigens. Conversely, susceptibility to VZV reactivation is not associated with decreasing titers of VZV IgG antibodies. Zoster in young children after intrauterine or early postnatal varicella and the short interval between primary and recurrent VZV infections in HIV-infected children probably reflects suboptimal induction of VZV cell-mediated immunity.^{32,128} Severe and prolonged suppression of VZV-specific cellular immunity creates the highest risk for zoster, viremia, and dissemination.

When reactivation occurs, VZV T-cell responses increase promptly, peaking at a responder cell frequency of about 10 per 100,000 PBMC at 6 weeks.⁶⁶⁹ The resolution of rash is also accompanied by local production of IFN- α in lesions.⁵⁹⁴ While information is limited, autopsy studies indicate that an extensive inflammatory response, including CD4, CD8, and NK cells, persists in ganglia for several months after zoster even without PHN.²¹⁴ Upregulation of CXCL10 occurs in ganglia during reactivation, and lymphocytes that express the CXCR3 receptor for CXCL10 are prominent among infiltrating cells⁵⁸⁸ (Fig. 63.11). Enhanced VZV T-cell immunity persists for at least 3 years after zoster⁶⁶⁹ and may explain why second episodes of zoster are rare.

EPIDEMIOLOGY

Incidence and Prevalence

VZV is a ubiquitous human pathogen with a worldwide geographic distribution. The annual incidence of varicella in the United States was equivalent to the annual birth rate (~4 million) before varicella vaccine was introduced in 1995,⁶⁷⁴ and the

prevalence of anti-VZV IgG antibodies indicates that up to 99% of adults are infected.³¹⁹ By 20 to 29 years of age, only about 5% of individuals remain susceptible in geographic areas with temperate climates. In tropical regions, only about half of individuals younger than 24 years of age have had varicella.^{186,396,478} The varicella attack rate is very high among susceptible adults who emigrate from tropical areas to temperate zones.

Given the high incidence of varicella, most adults are at risk for VZV reactivation and one-third will develop zoster. In the United States, approximately one million cases of zoster are diagnosed annually, two-thirds of which occur in individuals older than 50 years and nine in 10 are immunocompetent.⁷⁰¹ Hope-Simpson²⁶⁹ observed that the incidence rose to 7.8 cases per 1,000 people older than 60 years of age, compared with 2.5 per 1,000 people 20 to 50 years of age. The risk is as high as 50% among those who reach 85 years of age. Since the risk of zoster increases with age, and the population over age 65 is expected to be 72 million in 2030, zoster and its attendant serious neurologic complications will continue to be a significant health care burden.

Zoster incidence rates are equivalent between men and women but are lower in black than in white Americans.⁵⁶¹ Zoster is particularly frequent among patients with leukemia; Hodgkin's and non-Hodgkin's lymphoma; small-cell carcinoma of the lung; and after bone marrow transplantation (>25%) and renal transplantation (15%). Patients with systemic lupus erythematosus have an estimated incidence of 22 cases per 1,000 person years.^{398,487} HIV infection increases the risk for zoster by 15- to 25-fold regardless of age.^{60,192,208} Although cancer is correlated with a higher risk of zoster, zoster in healthy individuals is not associated with an increased risk for malignancy.⁵¹⁶ Zoster is rare in childhood, but varicella during the first year of life and infection *in utero* are associated with a higher risk.^{32,227,501}

Epidemic Patterns

Episodes of zoster provide a continuous source for VZV transmission to susceptible individuals, who then develop varicella. Varicella epidemics probably arise from sporadic cases in children after exposures to recurrent VZV in adults. Before varicella vaccination was introduced, most susceptible children became infected during annual epidemics due to efficient VZV transmission by the respiratory route and contact with high titers of infectious virus in skin lesions. The attack rate for previously uninfected household or day-care center contacts exposed to varicella is about 90%, compared to 12% to 33% for more casual exposures such as school classrooms.⁵⁹ Zoster is not seasonal because it originates from the reactivation of endogenous latent virus. Some reports have suggested that exposures to varicella can precipitate episodes of zoster, but there is no known mechanism by which reactivation would be triggered by re-exposure to the virus. While a zoster vaccine is available, only 6.7% of individuals over age 60 years have been immunized in the United States,³⁷⁹ leaving more than 900,000 of every one million individuals in this age group at risk for zoster.

Morbidity and Mortality

The high prevalence of VZV infection means that almost all individuals experience some VZV-related morbidity.^{72,674} The

risk for severe morbidity or mortality during primary or recurrent VZV infection depends on host factors rather than virulence characteristics of the virus.

Varicella complications resulted in hospitalization rates of 11,000 per year in the United States (2.2 to 4.3/1,000 cases) before varicella vaccine was introduced.⁷¹ Serious complications are least common among children 1 to 9 years of age and are 6 to 15 times higher among adults. Case fatality rates are 10 and 24 times higher in infants (6.7/100,000 cases) and adults (17.1/100,000 cases), respectively, than in children 1 to 4 years of age (0.7/100,000).⁴⁶⁴ Serious complications are usually secondary bacterial infections, varicella pneumonia in adults, or neurologic syndromes.^{169,228} CNS morbidity is higher among patients younger than 5 years and older than 20 years of age.²⁹²

Before effective antiviral drugs were available, 32% to 50% of children with malignancy developed visceral dissemination of the virus; varicella pneumonia occurred in 20% of cases, and the mortality rate was 7% to 17%.¹⁶⁵ Varicella occurs in 0.7 to 2 per 1,000 pregnancies, with a predicted maternal mortality rate of 0.5 per 1,000 cases¹⁵⁴ and a risk of congenital varicella syndrome. Rarely, the pregnancy may terminate by spontaneous abortion, fetal demise, or premature delivery.³⁵ The incidence of congenital varicella syndrome was 0.4% when maternal varicella occurred from 0 to 12 weeks' gestation, compared with 2% for infection from 13 to 20 weeks' gestation.¹⁵⁴ The virus appears to be transmitted to the fetus during the second and third trimester of maternal varicella with about the same frequency as in the first trimester, but a study found no infants with congenital varicella syndrome or other morbidity at birth if the mother had varicella between 25 and 36 weeks of gestation.¹⁵⁴ Infants are at risk for neonatal varicella when maternal varicella occurs at the end of gestation, with an attack rate of about 20% unless antibody prophylaxis is given, and a 30% mortality rate without antiviral therapy.

One in 10 individuals with zoster experiences at least one zoster-related nonpain complication, while one in four experiences zoster-related pain that persists 30 days or more.⁷⁰¹ The frequency of PHN is higher in older patients, increasing from 3% to 4% in those between 30 to 49 years of age to 21%, 29%, and 34% in patients 60 to 69, 70 to 79, and more than 80 years of age, respectively.^{18,679} Recent data from the United States indicate a risk of PHN of 1.38 cases per 1,000 person-years in healthy adults older than 60 years.⁴⁸² The annual medical care cost of treating zoster is estimated at \$1.1 billion, most of which is spent to treat immunocompetent adults 50 years and older.⁷⁰⁰ The incidence of zoster-associated CNS disease, most of which are cases of VZV vasculopathy, ranges from 0.2% to 0.5%, with risk factors including older age and cranial nerve involvement during the acute zoster episode. Cerebral angitis following zoster has a case-fatality rate as high as 20%. Immunosuppressive therapy for malignancy increases the morbidity and mortality associated with zoster, although the risk for fatal infection is less than 1%. Zoster is not unusual in pregnancy, but it does not cause significant maternal or fetal morbidity.¹⁵⁴

CLINICAL FEATURES

Varicella

Varicella follows an incubation period that ranges from 10 to 21 days. Prodromal symptoms of fever, malaise, headache, and

abdominal pain often precede the appearance of the rash by 24 to 48 hours. Fever, irritability, lethargy, and anorexia are prominent during the 24 to 72 hours after the first cutaneous lesions are noted; respiratory symptoms and vomiting are unusual. Body temperature usually rises to less than 101.5°F but can be as high as 106°F. The varicella exanthem begins on the scalp, face, or trunk. The cutaneous lesions consist of erythematous macules that evolve rapidly (within several hours) to form a clear, fluid-filled vesicle surrounded by an irregular erythema margin, the classic “dew drop on a rose petal.” (Fig. 63.1). Lesions in the maculopapular or vesicular stages are usually intensely pruritic. After 24 to 48 hours, the vesicular fluid becomes turbid, the lesions umbilicate, and crusting begins. Later crops of lesions form on the trunk and subsequently the extremities, and can resolve without progressing to form vesicles. Lesions of the mucous membranes of the oropharynx, conjunctivae, and vagina are common. In the final phase, the crusted lesions are sloughed as new epithelial cells are generated at the lesion site. Varicella vesicles are common on eyelids and conjunctivae, but eye disease is unusual.¹⁵¹

New varicella lesions emerge for 3 to 6 days, with the total number of lesions ranging from less than 10 to 2,000; most children have fewer than 300 lesions. True subclinical varicella is rare.⁵³⁶ Children who develop varicella after household exposure to an index case are more likely to have more severe varicella.^{142,536} Skin damage such as eczema or sunburn exacerbates the severity of the exanthem. Hypopigmentation of the skin at sites of varicella lesions often persists for several weeks, but extensive scarring is unusual. Low polymorphonuclear leukocyte and lymphocyte counts during the first 72 hours of rash are followed by lymphocytosis⁶¹; slight elevations of liver function tests are common.

Staphylococcus aureus and *Streptococcus pyogenes* (group A β -hemolytic streptococcus) cause secondary bacterial infection of skin lesions, cellulitis, bacterial lymphadenitis, or subcutaneous abscesses.^{61,116,169,226,286,490,500,681,682} (eFig. 63.4). Varicella gangrenosa, a form of necrotizing fasciitis, is a life-threatening infection usually caused by *S. pyogenes*.^{57,713} Bacteremia, usually caused by *S. aureus* or *S. pyogenes*, can lead to acute bacterial sepsis or focal infection such as pneumonia, arthritis, or osteomyelitis.

Varicella pneumonia in otherwise healthy adults^{468,511,644} presents with fever, cough, tachypnea, and dyspnea beginning about 3 days (range 1 to 6 days) after the onset of rash and may be associated with cyanosis, pleuritic chest pain, or hemoptysis (eFig. 63.5). Varicella pneumonia is often transient, resolving completely within 24 to 72 hours, but interstitial pneumonitis with severe hypoxemia progresses rapidly to cause respiratory failure in severe cases. Varicella pneumonia is associated with active infection of the epithelial cells of the pulmonary alveoli. Infection induces mononuclear cell infiltration of the alveolar septa and edema of alveolar septal cells, along with the accumulation of exudate, formation of hyaline membranes, and cellular desquamation into the alveolar spaces, which inhibit oxygen transfer. Desquamated septal cells in the alveoli and bronchiolar epithelial cells contain eosinophilic intranuclear inclusions and virions. Focal necrosis is characteristic of fatal varicella pneumonia.

Varicella hepatitis is associated with extensive replication in the liver, lysis of hepatocytes, and inflammation. Varicella hepatitis can occur subclinically, although it may be associated

with severe vomiting. Aspirin is contraindicated in children with varicella because it predisposes to liver damage (Reye's syndrome).

Varicella encephalitis or cerebellar ataxia usually occurs within 2 to 8 days.^{147,292,333,499,643} Patients with encephalitis typically have sudden onset of seizures and altered sensorium, whereas those with cerebellar disease show irritability, nystagmus, and gait and speech disturbances. Some patients have fever, headache, and meningismus only, without altered consciousness or seizures. The cerebrospinal fluid (CSF) usually shows a mild lymphocytic pleocytosis (<100 cells/mm³) and a slight to moderate protein level (<200 mg) with normal glucose. Encephalitic symptoms usually resolve rapidly (within 24 to 72 hours); ataxia can persist for days to weeks. A few cases of optic neuritis, transverse myelitis, and Guillain-Barré syndrome have been associated with varicella.^{198,292,374} Varicella encephalitis is observed most often in immunocompromised patients who have persistent viremia, suggesting a role for direct viral invasion of CNS tissue in some cases. The detection of herpesvirus particles and viral DNA in cerebrospinal fluid supports this possibility. The histopathology of brain tissue from rare cases of fatal varicella encephalitis demonstrates vasculitis of large and small vessels, demyelination, axonal damage, perivascular infiltration with mononuclear cells, microglial proliferation, and neuronal degeneration; however, histologic abnormalities are often minimal.^{11,333} In other cases, varicella-related neurologic syndromes resolve rapidly and completely, which may indicate a predominantly inflammatory or immune-mediated pathogenesis. The observation that cerebellar ataxia and encephalitis can occur during the pre-eruptive phase of varicella may indicate early transfer of VZV to neural tissues, triggering local inflammatory responses.^{373,643} CNS disease may also result from ischemic arteriopathies; one-third of these cases in children are associated with varicella.^{11,54,86}

Acute thrombocytopenia is a complication of varicella that causes petechiae and purpuric skin lesions, hemorrhage into the varicella vesicles, epistaxis, hematuria, and gastrointestinal bleeding. Hemorrhagic complications are usually transient. Purpura fulminans, caused by arterial thrombosis and hemorrhagic gangrene, is a rare but life-threatening complication. Thrombocytopenia may occur from 1 to 2 weeks or longer after varicella, as a result of direct infection of bone marrow megakaryocytes or immune-mediated processes. Platelet survival may also be reduced as a result of endothelial cell damage caused by vasculitis or transient hypersplenism, or as part of the syndrome of intravascular coagulopathy. As a postinfectious complication, thrombocytopenia may be associated with increased production but shortened platelet survival due to antiplatelet antibodies.

Varicella nephritis causes hematuria, proteinuria, diffuse edema, and decreased renal function, with or without hypertension. A few cases of nephrotic syndrome and hemolytic-uremic syndrome have been reported in children with varicella. Varicella arthritis is rare; it resolves spontaneously within 3 to 5 days with no residual joint disease. Other unusual complications of varicella include myocarditis, pericarditis, pancreatitis, and orchitis. Adrenal infection, characterized by focal necrosis, is common in fatal disseminated varicella. Renal pathology can occur, with hypercellularity of the glomeruli, epithelial proliferation, focal necrosis and interstitial inflammation.

Varicella in High-Risk Populations

Varicella vesicles in immunocompromised children are usually larger and more numerous, and new lesion formation often continues for at least 7 days, with an average time to lesion crusting of 14 days.⁶⁷⁷ In one series, all of the deaths from varicella in children with leukemia occurred within 3 days after the diagnosis of varicella pneumonia.¹⁶⁵ Varicella hepatitis and thrombocytopenia lead to coagulopathy; hemorrhage into lesions is a sign of severe varicella, as is severe abdominal or back pain. Encephalitis is rarely the immediate cause of death. Disseminated VZV infection in children with cancer has also produced myocarditis, nephritis, pancreatitis, necrotizing splenitis, esophagitis, and enterocolitis. Neutropenia enhances susceptibility to secondary bacterial infections. Children who acquire varicella after organ transplantation are also at risk for progressive VZV infection.^{178,263} Children on long-term, low-dose steroid therapy for asthma are not usually at risk for serious varicella,⁵⁸⁷ but fatal varicella has been described in patients receiving higher doses of prednisone during the incubation period.

Untreated varicella can be fatal in children with severe combined immunodeficiency or T-cell disorders, including adenosine deaminase or nucleoside phosphorylase deficiency and cartilage hair hypoplasia and NK-cell deficiencies.¹⁶¹ Varicella can also be severe in children with Wiskott-Aldrich syndrome or ataxia telangiectasia. Children with HIV infection may have unusual hyperkeratotic lesions and new lesion formation for weeks or months.^{128,192,225,297,307,353,608}

Placental infection with chronic villitis has been described after maternal varicella in pregnancy.⁵³³ VZV can be transmitted to the fetus, and in rare instances, causes congenital varicella syndrome (eFig. 63.6). Infants with congenital varicella syndrome have unusual cutaneous defects, with cicatricial skin scars, atrophy of an extremity, microcephaly, seizures, mental retardation, intrauterine growth retardation, and other sequelae, including chorioretinitis, micro-ophthalmia, and cataracts.^{35,154,507} Varicella embryopathy exemplifies the consequences of VZV infection of spinal ganglion cells and damage to the developing autonomic nervous system. Severe microcephaly with cortical atrophy and calcification follows intrauterine encephalitis and necrosis of brain parenchyma.

Varicella in the newborn period can be progressive, exhibiting the pathologic changes observed in other immunocompromised patients. Infants with neonatal varicella whose lesions are present at birth or within the first 5 days of life are not at risk for severe disease, probably because of transplacental transfer of maternal IgG antibodies to VZV. Those who are born within 4 days before, or 2 days after, the onset of maternal varicella may develop progressive varicella with hepatitis, pneumonia, and coagulopathy.

Zoster

Zoster is characterized by pain and a vesicular eruption on an erythematous base in one or several dermatomes (Fig. 63.1). Rash and pain usually develop within a few days of each other, although pain may precede rash by 7 to more than 100 days. The initial cutaneous lesions often appear in groups at one or several sites anteriorly and posteriorly within each affected dermatome; discrete vesicles resembling varicella lesions may merge to form larger, fluid-filled lesions as the exanthem evolves. Skin lesions resolve within 1 to 2 weeks, while

complete cessation of pain usually takes 4 to 6 weeks. Disseminated cutaneous lesions occasionally accompany the localized dermatomal infection even in the normal host. Many patients with uncomplicated zoster have a CSF pleocytosis and elevated protein. VZV can be isolated from CSF and detected by PCR.^{86,233,509} VZV reactivation in the immunocompromised host often causes a more extensive dermatomal rash and cell-associated viremia,¹⁶⁴ which allows VZV dissemination to lungs, liver, CNS, and other organs. Dissemination can occur without rash, suggesting that T cells can become infected while trafficking through the infected ganglia. Patients with HIV infection may have chronic hyperkeratotic skin lesions (eFig. 63.7).

Because VZV becomes latent in any ganglion, zoster can develop in any dermatome. The trunk from T3 to L2, which is innervated by twelve pairs of ganglia, is the most frequently involved (Table 63.2), followed by the face and the extremities. The face, which is the second most common site, is supplied by

Each dot represents a single case of zoster.
(From Hope-Simpson RE. The nature of herpes zoster: a long-term study and a new hypothesis. *Proc R Soc Med* 1965;58:9–20, with permission.)

afferent fibers only from the two trigeminal ganglia; these are the most frequently latently infected ganglia,⁴⁵⁵ as is the case for HSV-1. In the classic study by Hope-Simpson,²⁶⁹ about half of the cases involve the thoracic dermatomes, particularly T5 to T12. Lumbosacral dermatome disease was observed in 16% of these patients, predominantly in the L1 to L2 distribution. HSV reactivations in this region are patchy rather than dermatomal (Fig. 63.13).

Zoster affects the head in approximately 19% of cases, with nearly all rashes (97%) in the trigeminal distribution.^{62,269} In patients with trigeminal zoster, the ophthalmic division of the fifth nerve is most frequently affected (eFig. 63.8). There have been 14 reported cases of trigeminal zoster accompanied by alveolar bone necrosis and tooth loss.³⁹⁷ The seventh cranial nerve ganglion is the next most commonly affected. Weakness of facial muscles is usually associated with lesions in the ear (Ramsay Hunt syndrome; geniculate zoster). Vesicles may also be observed on the anterior two-thirds of the tongue.⁴⁹¹ Commonly associated with geniculate zoster are eighth-nerve deficit,¹¹⁵ fifth-nerve zoster or zoster of the occiput and neck,³³⁴ ophthalmoplegia,⁶¹⁹ and multiple lower cranial nerve palsies.^{116,590} Importantly, multiple forms of VZV reactivation in a trigeminal^{146,264,691} and facial^{433,448,617} distribution as well as polyneuropathy^{450,480} may occur in the absence of rash.

The mechanism by which the cranial nerves are involved in zoster is not clear. Examination of one case with oculomotor nerve involvement and death 4 days after cutaneous signs revealed neuronal degeneration, with microglial and lymphocytic infiltration in the oculomotor nuclear complex, and a leptomeningeal infiltrate most marked over the lower medulla and at the point of entry of the trigeminal and oculomotor nerve roots.²¹² Orbital changes consisted of perineural and intraneural lymphocytic infiltrates of the retrobulbar, episcleral, and intrascleral segments of the long posterior ciliary nerves, with minimal lymphocytic infiltrates and sarcolemmal proliferation in extraocular muscles. Thus, cranial neuropathy may be due to a circumscribed myositis or lymphocytic mononeuropathy. PHN, the most common neurologic complication of zoster, is often defined clinically as pain that persists for at least 3 months after resolution of zoster rash. Age is the most important factor in predicting the development of PHN. Pain is usually constant, severe, stabbing or burning, and frequently associated with allodynia (increased sensitivity to light touch). The incidence of PHN appears to be slightly higher in women²⁷⁰ and after zoster involving the trigeminal ganglia.^{125,535} VZV reactivation can also produce chronic radicular pain without rash (zoster sine herpete) as well as other zoster-related neurologic and ocular disorders in the absence of rash.

Zoster paresis (weakness) is manifest by arm weakness or diaphragmatic paralysis^{58,602} after cervical distribution zoster, leg weakness after lumbar or sacral distribution zoster, and by urinary retention after sacral distribution zoster.^{283,289} Magnetic resonance imaging (MRI) reveals involvement not only of the posterior horn and posterior roots, but also of the anterior roots and anterior horn at the spinal level corresponding to the clinical deficit.^{240,630} Rarely, clinical deficit in cervical zoster paresis extends to the brachial plexus.⁸⁴ The prognosis varies. In one series of 45 patients with zoster paresis, 67% had near-complete recovery,²³¹ and in another 61 cases, 55% had complete functional recovery.⁶¹⁹

VZV reactivation may also present as meningitis or meningoencephalitis. Many reported cases of VZV encephalitis

may actually be VZV vasculopathy.¹⁹⁹ Recent reports of VZV meningitis,^{234,331} meningoencephalitis,²³⁰ and cerebellitis (gait ataxia and tremor predominated)^{447,520}—all in the absence of rash and confirmed by the detection of VZV DNA or anti-VZV antibody in CSF—reveal that VZV is not an uncommon cause of aseptic meningitis.

VZV produces multiple ocular disorders, including both acute retinal necrosis (ARN) and progressive outer retinal necrosis (PORN) (Fig. 63.16).^{301,663,679} ARN develops in both immunocompetent and immunocompromised hosts, with patients exhibiting periorbital pain and floaters with hazy vision and loss of peripheral vision. PORN presents with sudden painless loss of vision, floaters, and constricted visual fields with resultant retinal detachment. Multifocal, discrete opacified lesions begin in the outer retinal layers peripherally and/or posterior pole; only late in disease are inner retinal layers involved. Diffuse retinal hemorrhages and whitening with macular involvement bilaterally are characteristic findings (Fig. 63.16). Although PORN can also be caused by HSV and cytomegalovirus, most cases are produced by VZV in AIDS patients with CD4+ counts less than 10 cells/mm³²²⁹ as well as in other immunosuppressed individuals.³⁶³ PORN may be preceded by retrobulbar optic neuritis and aseptic meningitis,¹⁷⁴ central retinal artery occlusion or ophthalmic-distribution zoster,⁴¹³ and may occur together with multifocal vasculopathy or myelitis. Optic neuritis after zoster may be bilateral.^{418,566} Reports of visual loss in association with pain on eye movement and clinical findings of papillitis and central scotomata or optic atrophy weeks after VZV infection suggest an immunologic pathogenesis in some cases.⁶⁷ The third nerve is affected more frequently than the sixth as a cause of zoster ophthalmoplegia. Least affected is the fourth, although isolated VZV-associated trochlear nerve palsies have been described.²¹⁸ Combinations of third, fourth, and sixth nerve palsies are not unusual. Like optic neuritis, ophthalmoplegia often appears weeks to months after cutaneous signs.^{149,304}

VZV infection of cerebral arteries (VZV vasculopathy) is a serious complication of VZV reactivation, which causes both ischemic and hemorrhagic stroke. In adults with zoster, the risk of stroke was increased by 30% within the following year²⁹⁹ and 4.5-fold when zoster was in the ophthalmic distribution of the trigeminal nerve.³⁶⁹ VZV vasculopathy affects both immunocompromised and immunocompetent individuals and can present as headache, mental status changes, and focal neurologic deficits. Both large and small vessels are involved.⁴⁵⁶ Lesions at gray-white matter junctions are frequently seen on brain imaging (Fig. 63.16). In more than two-thirds of patients, angiography reveals focal arterial stenosis and occlusion, aneurysm, or hemorrhage. In 30 virologically verified cases of VZV vasculopathy, both large and small arteries were involved in 50%, small arteries in 37%, and large arteries alone in only 13%.

VZV vasculopathy produces bland or hemorrhagic infarctions. Deep white-matter lesions often predominate and are ischemic or demyelinating, depending on the size of blood vessels involved (Fig. 63.16). Case reports have revealed a wide range of vascular pathology, ranging from neointimal proliferation to necrosis with and without inflammation.³³² Infected cerebral arteries contain multinucleated giant cells, Cowdry A inclusion bodies, herpesvirus particles detected by electron microscopy, as well as VZV DNA and viral proteins. VZV

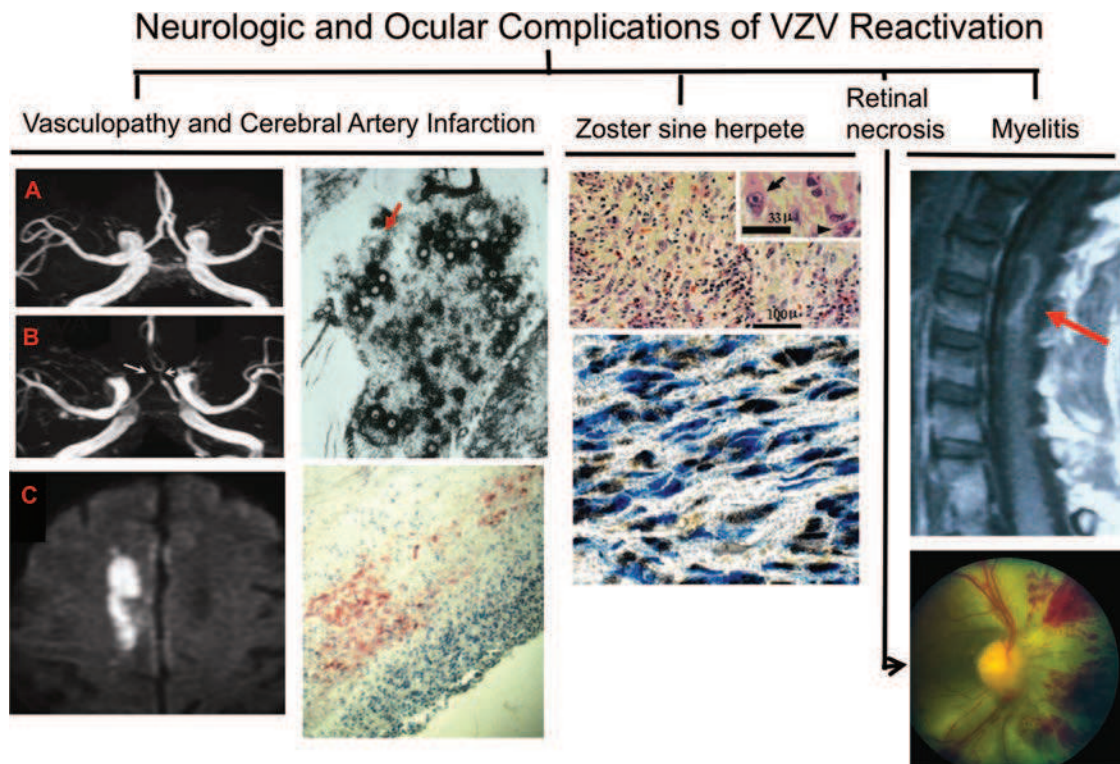

FIGURE 63.16. Neurologic and ocular complications of varicella-zoster virus reactivation. **A:** VZV-induced vasculopathy and infarction. Three-dimensional time-of-flight magnetic resonance angiography of the Circle of Willis 5 months before infarction shows normal anterior cerebral arteries (**a**), while the same analysis at the time of infarction (**b**) shows marked narrowing of anterior cerebral arteries, with a new flow gap at the junction of A1 and A2 segments of the right anterior cerebral artery, indicating occlusion on the right (*long arrow*) and marked stenosis on the left (*short arrow*). (**c**) Diffusion-weighted image (B value 1,000) shows restricted diffusion in the right anterior cerebral artery territory, indicating acute infarction. *Upper right:* Multiple herpes virions within a cerebral artery. *Lower right:* VZV antigen (red) in the media of a cerebral artery of a patient with VZV vasculopathy. **B:** Ganglionitis and intranuclear inclusions in zoster sine herpette. H&E staining of the trigeminal ganglion (*upper panel*) shows widespread chronic inflammation with fibrosis and loss of neurons. Cells in some foci contain Cowdry type A intranuclear inclusions (*arrow, inset*) indicative of virus infection; the inflammatory cells are mainly lymphocytes, with some plasma cells (*arrowhead, inset*). Immunohistochemical staining of the same ganglion (*lower panel*) with mouse monoclonal antibody against VZV IE63 indicates VZV antigen (*brown staining*) in multiple cells throughout the ganglion. Adjacent sections stained with antibody against HSV or with normal rabbit serum were negative (not shown). **C:** Fundus photograph of a patient with VZV vasculopathy and progressive outer retinal necrosis. Note the diffuse retinal hemorrhages and whitening, with macular involvement. **D:** MRI abnormality in a patient with VZV myelitis; note the longitudinal, serpiginous enhancing lesion.

vasculopathy predominantly affects intracranial rather than systemic arteries, possibly due to inherent cellular and structural differences. For example, intracranial cerebral arteries do not contain the external elastic lamina that may affect transmural migration of virus and cells.³⁵⁷ Like horseradish peroxidase, which migrates from the external surface of cerebral arteries to trigeminal ganglia,^{405,406} reactivated VZV may also travel along ganglionic afferent fibers to the adventitia of cerebral arteries, a concept supported by the presence of viral antigen predominantly in the adventitia of cerebral arteries in early VZV vasculopathy.⁵⁴⁵ Elements of VZV vasculopathy that may contribute to stroke include a thickened arterial intima composed of myofibroblasts and cells of medial smooth muscle origin, a disrupted internal elastic lamina, and decreased numbers of smooth muscle cells.⁴⁵⁸

VZV myelopathy, also called postinfectious myelitis, usually presents days to weeks after zoster as a self-limiting, monophasic spastic paraparesis, with or without sensory fea-

tures and loss of sphincter function. The CSF usually contains a mild mononuclear pleocytosis, with a normal or slightly elevated protein. Rarely, VZV myelitis recurs.¹⁹⁸ VZV myelopathy may also be an insidious, progressive and sometimes fatal myelitis, usually in immunocompromised individuals, especially those with AIDS. MRI reveals longitudinal serpiginous enhancing lesions (Fig. 63.16). Pathologic and virologic analyses of the spinal cord from fatal cases have shown frank invasion of VZV in the parenchyma³³² and in some instances, spread of virus to adjacent nerve roots.¹³⁰ Importantly, VZV myelitis may develop without rash. VZV-induced vasculopathy can also produce spinal cord infarction.⁴⁷⁹

Zoster sine herpette is chronic radicular pain without rash. The first two virologically confirmed cases were verified by detection of VZV DNA in CSF.^{198,201} A third case of thoracic-distribution zoster sine herpette, in which electromyography of paraspinal muscles demonstrated frequent fibrillation potentials restricted to chronically painful thoracic root segments,

was confirmed by detection of VZV DNA in blood MNCs and anti-VZV IgG antibody in CSF.¹² In a recent report of a patient with zoster sine herpete, the CSF did not contain amplifiable VZV DNA but did contain anti-VZV IgG, with reduced serum/CSF ratios of anti-VZV IgG indicative of intrathecal synthesis.⁴⁹ The most compelling evidence that persistent radicular pain without rash can be caused by a chronic active VZV ganglionitis came from analysis of a trigeminal ganglionic mass removed from an immunocompetent adult who had experienced relentless trigeminal distribution pain for more than 1 year; pathologic and virologic analyses (Fig. 63.16) revealed that the patient's zoster sine herpete was caused by an active VZV ganglionitis.²⁶⁴ Ocular disorders caused by VZV can also occur in the absence of rash. PORN,^{176,183} severe unremitting eye pain,²¹³ third cranial nerve palsies,²⁶⁵ retinal periphlebitis,⁴⁶⁹ uveitis,^{5,265} iridocyclitis,⁶⁹² and disciform keratitis⁵⁷⁶ have been confirmed to be caused by VZV without rash.

The detection of VZV DNA and anti-VZV IgG antibody with reduced serum/CSF ratios in the CSF of patients with meningoencephalitis, vasculopathy, myelitis, cerebellar ataxia, and polyneuritis cranialis, all without rash, has expanded the spectrum of neurologic disease produced by VZV in the absence of rash. An illustrative example is provided by the report of an immunocompetent 45-year-old woman with multiple episodes of neurologic disease (multifocal vasculopathy, meningoencephalitis, recurrent myelitis and inflammatory brain-stem disease) over an 11-month period produced by VZV in which the CSF contained anti-VZV IgG antibody, but not VZV DNA, throughout her illness.²⁴⁷

DIAGNOSIS

Differential Diagnosis

Varicella must be differentiated from vesicular rashes caused by enteroviruses or *S. aureus*, scabies, drug reactions, contact dermatitis or, rarely, rickettsial pox or disseminated HSV infection. The clinical diagnosis of zoster can be difficult when acute pain and paresthesias precede the cutaneous eruption; the pain can be sufficiently severe to mimic myocardial infarction, cholecystitis, appendicitis, and other conditions. Localized contact dermatitis is the most common alternative etiology. A recurrent vesicular rash in lumbosacral dermatomes is usually HSV infection.

Laboratory Diagnosis

Laboratory techniques are most useful to guide decisions about antiviral treatment for VZV infection, especially for high-risk patients and for the differential diagnosis of neurologic disorders.³⁵⁸ Methods for diagnosing varicella and zoster infections are described in Chapter 17. Briefly, the most sensitive method to identify VZV in any tissue is detection of viral DNA by PCR^{86,196}; VZV proteins can be identified by immunohistochemical analysis of cells from cutaneous lesions prior to crusting. Infectious virus can be isolated from lesion specimens in tissue culture but cultures are often negative, especially if the specimen is not processed rapidly or the lesions are later stage. Assays for VZV IgG antibodies are most useful for determining the immune status of individuals whose clinical history of varicella is equivocal.³⁴⁰ The fluorescent-antibody membrane antigen assay (FAMA) is the most sensitive and specific method and the only method documented to predict susceptibility.¹⁹⁶

Most commercial enzyme immunoassay methods have high specificity, generating few false-positive results, but 10% to 15% of immune individuals may be misidentified as susceptible. Commercial VZV IgM antibody assays often lack specificity and should not be used as the only evidence of VZV-related disease.

If VZV is considered a potential cause of a neurologic disorder without rash—for example, meningoencephalitis with or without cerebellitis, chronic radicular pain, vasculopathy, myelitis, or retinal necrosis—then CSF and blood MNCs should be tested for VZV DNA by PCR and CSF for anti-VZV antibody.^{12,206} VZV DNA is most likely to be found in patients with acute meningoencephalitis and cerebellitis and in some patients with VZV vasculopathy and myelitis. VZV vasculopathy is difficult to diagnose because many patients do not have a preceding zoster rash or CSF pleocytosis; VZV DNA PCR analysis of CSF is only 30% sensitive and symptoms often occur months after zoster.⁴⁵⁷ The best criterion to confirm VZV vasculopathy is detection of anti-VZV IgG and/or anti-VZV IgM in CSF or anti-VZV IgM in serum. Demonstration of the intrathecal synthesis of anti-VZV IgG antibodies indicates chronic active infection⁵²⁴ and is superior to detection of VZV DNA in CSF for diagnosis of VZV vasculopathy, recurrent VZV myelopathy, and zoster sine herpete.^{49,247,457}

TREATMENT

While human leukocyte interferon and vidarabine were the first antiviral treatments with clinical benefit,^{22,414} acyclovir and related drugs (see Chapter 14) are more effective and safer and are now used to treat both varicella and zoster.^{36,145,414,678} Two nucleoside analog prodrugs have been approved in the United States.^{46,626} Valacyclovir is a six-valine ester derivative of acyclovir that is de-esterified by hepatic enzymes to yield acyclovir. Famciclovir is a diacetyl derivative of penciclovir, a guanosine analog, which is enzymatically converted to penciclovir by intestinal and hepatic enzymes. These prodrugs are better absorbed from the gastrointestinal tract than are their parent compounds acyclovir and penciclovir, allowing higher serum levels of drug after oral administration.

Molecular proof of the pivotal role of the VZV TK in the action of acyclovir and penciclovir has come from both the cloning and stable expression of the gene in TK-deficient cells and from sequencing of the VZV gene in acyclovir-resistant viral mutants.^{556,613} Missense mutations in the TK ATP- or nucleoside-binding sites, and mutations clustered between these two sites confer acyclovir resistance. Nonsense mutations leading to expression of grossly truncated VZV TK protein also result in drug-resistant viruses. Rarely, acyclovir resistance can be conferred by mutations in the VZV DNA polymerase. VZV strains that are resistant to both acyclovir and penciclovir retain sensitivity to the pyrophosphate analog, foscarnet.⁵⁵ Cidofovir, an acyclic nucleoside phosphonate, is also active against acyclovir-resistant VZV strains and is an alternative to foscarnet.⁶³⁸

Sorivudine (1-β-D-arabinofuranosyl-E-[2-bromo-vinyl]uracil) is an oral drug with potent *in vitro* activity against VZV and is effective *in vivo* in healthy adults with varicella and HIV-infected patients with zoster, but it is not licensed in the United States because of toxicity resulting from interaction with 5-fluorouracil.^{50,209} Sorivudine also limits SVV infection.⁵⁷⁸ However, the marginal benefit of this drug over acyclovir in HIV-infected

patients with zoster suggests that early administration is more important than potency of the antiviral drug. Whereas all of the licensed antiviral drugs that inhibit VZV replication act on the viral DNA polymerase, other as yet unapproved compounds have different targets. A thiourea compound inhibits VZV by interfering with VZV ORF54 protein, the putative portal protein, and encapsidation of viral DNA.⁶³⁶ Roscovitine, an inhibitor of cyclin-dependent kinases, also inhibits VZV replication in cultured cells.⁶¹⁴ New agents that target host-cell proteins and restrict VZV replication *in vitro* and in human tissue xenografts have also been identified.⁵⁴⁰

Varicella

Acyclovir therapy diminishes the clinical severity of varicella in immunocompromised children by ensuring that cell-associated viremia is terminated, despite an impaired host response. Early therapy prevents progressive varicella and visceral dissemination.⁵⁰⁸ In addition to preventing life-threatening dissemination, early acyclovir therapy minimizes cutaneous disease and may therefore reduce the risk of secondary bacterial infections. Immunocompromised patients who have pneumonia, hepatitis, thrombocytopenia, or encephalitis require immediate treatment with intravenous acyclovir.⁶⁷⁷

Oral acyclovir ameliorates varicella symptoms in healthy children, adolescents, and adults when administered within 24 hours after the appearance of the initial cutaneous lesions.^{10,142,644} Adults with varicella pneumonia, including pregnant women, require immediate treatment with intravenous acyclovir. Acyclovir therapy does not prevent the host from mounting an effective immune response to VZV, consistent with the concept that limited viral replication provides sufficient antigenic stimulation to induce VZV memory immunity.

Zoster

Acyclovir and the related drugs are beneficial therapies for zoster in healthy and immunocompromised patients. Among healthy individuals, treatment initiated within 72 hours reduces the period of continued new lesions in the involved dermatome and the time to complete healing.^{677,685} Antiviral treatment is especially important in immunocompromised patients because of their risk of disseminated disease, and for adults with ophthalmic zoster because of their risk for developing acute uveitis and chronic keratitis. All patients with ocular disease caused by VZV should have an immediate evaluation by an ophthalmologist. Acute neuropathic pain is reduced by early treatment with acyclovir, valacyclovir, or famciclovir; effects on chronic PHN are less obvious. The benefits of antiviral therapy for limiting acute rather than chronic pain suggest that different mechanisms may contribute to these two components of zoster-related pain.⁶⁷⁹

Acyclovir is usually given intravenously to immunocompromised patients who are at high risk for disseminated zoster; less severely immunocompromised patients are given the oral prodrug valacyclovir or famciclovir. Treatment reduces the duration of new lesion formation, acute pain and time to complete healing; some benefit is observed even when therapy is delayed for more than 72 hours because the pathologic process is more extensive in these patients.^{36,303,678} Although acyclovir therapy usually eliminates the risk for visceral dissemination, relapse of zoster occurs in some immunocompromised patients.²⁸⁷ Most

patients respond to treatment with a second course of acyclovir, indicating that relapse reflects an inadequate host response rather than antiviral resistance.^{287,371}

While not life-threatening, PHN is difficult to treat. Neuroleptic drugs and various analgesics, including opiates, are used to alleviate pain, but no universally accepted treatment exists. Drugs include pregabalin, oxycodone, morphine sulfate, tricyclic antidepressants such as amitriptyline, nortriptyline, maprotiline and desipramine, and levorphanol.^{138,538,539} Morphine and gabapentin in combination decreases pain more than either drug alone or placebo.²⁰⁷

Patients with VZV vasculopathy can be treated with intravenous acyclovir and prednisone. Steroids are also used to treat patients with myelopathy,⁵⁰⁴ although some improve spontaneously.⁷⁰ Some patients with myelitis respond to antiviral therapy^{85,129,565}; the benefit of steroids in addition to antiviral agents is unknown. PORN is treated with intravenous acyclovir, steroids, and aspirin followed by oral acyclovir.⁵¹ Intravitreal injections of foscarnet and oral acyclovir have been used in early milder cases, although retinopathy may persist or recur despite acyclovir treatment.²⁹¹ PORN patients given ganciclovir alone or combined with foscarnet had a better final visual acuity than those treated with acyclovir or foscarnet.⁴³² AIDS patients given highly active antiretroviral therapy (HAART) appear to have less risk of PORN.¹⁶

PREVENTION

In most circumstances, preventing VZV transmission to susceptible individuals is difficult because patients with varicella may be contagious for 24 to 48 hours before the onset of their rash. Infection control practices, including caring for infected patients in isolation rooms with filtered air systems, are essential in hospitals that treat patients for whom varicella might be life-threatening.^{354,555}

Passive Antibody Prophylaxis

Varicella zoster immunoglobulin (VZIG) is no longer available; the related product, VariZIG,⁷³ is prepared from high-titer immune human serum. High-dose intravenous immunoglobulin may also be used for passive immunization. VZV antibody prophylaxis is recommended to reduce the occurrence of infection or disease severity in individuals with risk factors for serious varicella and recently exposed to a person with acute varicella or zoster.^{10,73} To be effective, prophylaxis must be given within 96 hours and preferably within 48 hours after exposure.¹⁰ VZV antibody prophylaxis does not eliminate the possibility that primary VZV infection will occur.^{419,704} Even with prophylaxis, the incidence of varicella is higher after household exposures and is related to the VZV IgG titer of the preparation. Passive antibody prophylaxis does not reduce the risk for VZV reactivation in high-risk populations, and passive antibody administration after the onset of illness does not alter the severity of varicella or zoster.⁵⁹⁴

Antiviral Prophylaxis

Administration of acyclovir during the incubation period following exposure of susceptible individuals to VZV can prevent disease if given early; however, the benefit of using acyclovir for prophylaxis has not been compared directly with acyclovir

treatment of individuals in whom the varicella rash has just erupted.^{204,460} Daily administration of oral acyclovir for 12 to 24 months can diminish the risk of zoster in bone marrow transplant recipients,^{620,677} but zoster occurs when acyclovir is discontinued and drug-resistant VZV mutants may emerge. The alternative is prompt initiation of acyclovir for VZV reactivation.⁴⁹⁸

Vaccines

Varicella

The live attenuated varicella vaccine is the first and remains the only human herpesvirus vaccine licensed for clinical use in several countries.^{236,341} Its development and initial clinical evaluation were first reported by Takahashi in 1974.^{610,611} The vaccine virus was derived from a clinical isolate of VZV, the Oka strain, which was propagated in guinea pig embryo fibroblasts and then in WI38 human fibroblasts. In contrast to the outcome in susceptible children inoculated with infectious VZV from vesicular fluid,⁶⁴¹ tissue-culture propagation appears to attenuate the virus so that vaccine containing as much as 17,000 plaque-forming units (pfu) per dose of infectious virus induces immunity to VZV but rarely produces clinical symptoms.⁶⁶⁷ Attenuation is maintained, although varicella vaccine stocks contain mixtures of VZV genomes with varying mutations.⁵⁶² Experiments comparing the parent Oka and vaccine Oka viruses in the SCID mouse model indicate that passage in fibroblasts reduces the ability of the virus to replicate efficiently in human skin, although T-cell tropism and neurotropism are not affected.^{427,707} Less than 5% of children develop skin lesions after vaccination with Oka-derived vaccines; however, the vaccine Oka strain of VZV can be transmitted from these individuals.^{19,145,350,351,427,428} (eFig. 63.9). Whether the virus remains attenuated is not known because of the low frequency of secondary cases. When the vaccine virus was transmitted from a healthy child to a pregnant contact, no laboratory evidence indicated transplacental transmission,⁷¹ consistent with the low risk for wild-type VZV spread across the placenta.

In prelicensure clinical trials, the live attenuated (Oka-Merck strain) vaccine was administered to more than 7,000 children and more than 1,600 healthy, susceptible adults.^{246,366,675} It is now recommended for routine vaccination of infants and susceptible older children and adults in the United States.¹⁰ In the clinical trials, a single dose of vaccine containing 1,000 to 3,000 pfu of attenuated Oka virus induced seroconversion rates of more than 90% in children 12 years of age and younger, and afforded complete protection against disease in about 85% of exposures. On exposure to varicella, some previously vaccinated children experience breakthrough infection, but the resulting disease usually remains mild, with fewer than 50 cutaneous lesions and no associated fever.^{181,284,662} Modified disease severity is consistent with priming of the host response by immunization. The varicella vaccine also induces VZV-specific cellular immunity,^{454,661} which is likely to be essential for its long-term protective efficacy.^{134,570} Varicella immunization elicits T cells that proliferate and produce lymphokines in response to stimulation with the IE62 protein and the viral glycoproteins^{30,43} and induces cytotoxic T cells that can lyse cells expressing VZV proteins.^{290,571} The VZV-specific T-cell response occurs shortly after vaccination, with VZV-specific T cells detectable within 10 to 14 days in most indi-

viduals.²⁹ In contrast, IgG antibodies to VZV were detected in only 40% of children tested at 2 weeks. This early T-cell response may account for the efficacy of vaccination when given immediately after exposure.²⁹ Varicella vaccine is also immunogenic when administered concurrently with measles-mumps-rubella (MMR) vaccines or as a quadrivalent MMR-V vaccine, although the risk of febrile seizures is increased after the first dose of the quadrivalent vaccine.^{155,572}

Achieving high VZV IgG seroconversion rates in susceptible adolescents and adults requires two doses of the vaccine administered at an interval of at least 4 weeks,^{194,454} consistent with the evidence of a diminished host response to primary VZV infection and more severe varicella in adults. However, cellular immunity to VZV in adults given two doses of vaccine was significantly lower compared with children who received a single dose of vaccine, and VZV-specific T-cell proliferation correlated with lower IFN- γ responses.^{290,454} Adults are also more likely than children to have adverse effects to the vaccine, particularly transient local reactions and rash, and to have waning VZV antibody titers. Despite their less robust immune responses, susceptible adults are at risk of developing serious varicella, and protection from or modified severity of the illness by vaccination is documented.¹⁸⁹

The persistence of VZV memory immunity after immunization has been difficult to assess because the continued circulation of wild-type VZV provides opportunities for boosting vaccine-acquired immunity through exogenous exposure. However, VZV IgG and T-cell responses have been documented in 94% to 100% of varicella vaccine recipients for 7 to 10 years after vaccination, and protection has been sustained in most vaccinees.^{13,194,346,464,571,635} In postlicensure surveillance done before vaccine coverage rates were high, no change in the frequency of breakthrough varicella or severity of symptoms with time after vaccination was found; however, those with low or undetectable VZV IgG titers 6 weeks after immunization were four times more likely to experience varicella. Prelicensure studies showed that a two-dose regimen induces higher humoral and cellular immune responses in children evaluated just after vaccination and after 1 year.^{454,495}

Although the incidence of varicella is dramatically lower in all age groups in the United States, the widespread use of the varicella vaccine has meant that as many as half of the cases of varicella in well-vaccinated populations are in immunized children. Because the wild-type virus is transmissible from cases of breakthrough varicella, community outbreaks can be sustained. The observations of the enhanced host response to two doses, along with the surveillance data on breakthrough infections, has led to the use of a two-dose regimen in children as well as in adolescents and adults. Varicella immunization using a two-dose regimen of MMR-V also enhances the primary immune response to the varicella component.⁵⁷²

The Oka-Merck varicella vaccine has also been given to children with acute leukemia in remission, reducing the attack rate after household exposure to 13%.^{192,194} Seroconversion in these patients is associated with a high degree of protection after two doses of vaccine. Cell-mediated immunity is elicited less reliably in leukemic children given varicella vaccine, consistent with the often diminished T-cell proliferation to VZV antigens after natural varicella in immunocompromised children.¹⁹² Because it contains infectious virus, varicella vaccine must be given to these children with careful attention

to the status of their underlying disease and immunosuppressive therapy regimens.²⁷⁷ Vaccine-related rashes occurred at about 1 month after immunization in ~50% of children with leukemia in remission. Rashes occurred at the site of inoculation but also as widely scattered vesicles, indicating that the vaccine virus remains capable of causing cell-associated viremia. This experience is consistent with the finding that the vaccine retains tropism for T cells in the SCID mouse model. In healthy children, the limited replication of the vaccine virus at the site of subcutaneous inoculation likely allows time for induction of adaptive VZV-specific immunity before viremia can occur, whereas vaccine virus may escape from infected epithelial cells into T cells, causing viremia and varicella-like symptoms in some immunocompromised children.¹³ When children with leukemia developed rash, the vaccine virus was transmitted to their healthy, susceptible siblings, but the contacts had mild illness or asymptomatic seroconversion.¹⁹² That vaccine virus was not transmitted unless the immunocompromised child had rash indicates that no significant replication of the vaccine virus occurred at respiratory sites.⁶²² Immunizing susceptible, healthy household contacts of high-risk children may also reduce the risk of household exposure.^{134,546} VZV was detected by PCR in oropharyngeal secretions from 7% of children given varicella vaccine in Japan, but no infectious virus was recovered.⁴⁸⁴

Reactivation of the vaccine strain of VZV has been described in a few healthy vaccine recipients; however, analysis of the incidence of zoster in leukemic children who had vaccine-induced immunity and in those with past natural infection showed that the vaccine virus reactivated significantly less often than wild-type VZV.²⁴² Whether this observation indicates that the vaccine virus is less likely to establish latency or has less potential for reactivation is not known. VZV-specific T-cell responses were higher in leukemic children who had been vaccinated but did not experience recurrent VZV compared with children who developed zoster.³⁵² If symptomatic reactivation does occur, the vaccine virus can be inhibited by acyclovir. Vaccinated individuals can also develop zoster through subclinical infection with wild-type VZV despite vaccine-induced immunity.²³⁷ Information about the prevalence of vaccine or wild-type VZV in neurons after immunization is limited, but VZV was detected by PCR in ganglia from children who died from trauma or nonimmunocompromising conditions.¹⁸⁹ If use of the varicella vaccine in early childhood continues to greatly diminish the annual varicella epidemics, as has occurred in the United States, exposures should be reduced significantly and opportunities for superinfection with wild-type VZV will be minimal. If exogenous exposures are important for maintaining memory immunity in individuals with naturally acquired infection, then zoster might become more common in highly vaccinated populations, although current evidence argues against this possibility.^{357a}

Zoster

The development of the varicella vaccine raised the possibility that vaccination might also be effective for reducing the risk of zoster associated with waning immunity in the elderly.⁴⁸² When high-potency VZV vaccine was given to healthy older adults, VZV-specific responder cell frequencies increased from 1 per 68,000 to 1 per 40,000 in healthy adults over 55 years of age, which was equivalent to the VZV responder cell numbers in naturally immune individuals aged 35 to 40 years.³⁶¹

Administration of the vaccine to elderly individuals was associated with increased production of IFN- γ by T cells stimulated with VZV antigen and recovery of skin test reactivity to VZV antigen in most vaccinees.³⁶ To avoid risks associated with infectious virus, a heat-inactivated preparation of varicella vaccine was given to patients receiving autologous bone marrow transplantation; recovery of VZV T-cell immunity was accelerated and zoster was less common in vaccinated transplant recipients as compared with unvaccinated controls.²⁴⁸

A high-potency preparation of the live attenuated VZV vaccine has now been shown to reduce the morbidity of zoster significantly in healthy adults aged 60 years and older.⁴⁸² This vaccine contains about 14-fold more attenuated Oka virus than the pediatric vaccine. Comparison of vaccinees and placebo recipients in a large randomized trial of almost 40,000 subjects showed a reduction in the burden of zoster illness, considering both incidence and severity of disease, by 61.1% ($P < 0.001$) over a median follow-up period of 3 years. The incidence of PHN was reduced by 66.5% ($P < 0.001$) and zoster incidence decreased by 51.3% ($P < 0.001$) in zoster vaccinees (Fig. 63.15). Mild injection-site reactions were more common in vaccinees compared with placebo recipients, but no significant adverse events attributable to the vaccine were observed. Although the impact of vaccination on zoster occurrence was more substantial in participants aged 60 to 69 years compared with those 70 years and older, both groups benefitted clinically because the older subjects who are more likely to develop PHN experienced less PHN with the vaccine. This study demonstrates that VZV-specific immunity can be boosted in older adults and can reduce the risk of VZV reactivation or prevent its clinical consequences. The vaccine is also approved for zoster prevention in those aged 50 to 59 years based on an efficacy study of 22,000 adults although routine use in this age group is not recommended at this time.^{73a}

PERSPECTIVE

Many new insights about VZV genomics, replication, specific gene functions and virus–host interactions have been gained over the past decade. Infectious VZV genomes can be generated using cosmids and BACs and can be readily mutated to assess gene functions and their regulation. Because the VZV genome can express foreign genes and because the varicella vaccine has proved to be safe, VZV is now being considered for use as a vaccine platform and has been engineered to express Epstein-Barr virus gp350, hepatitis B surface antigen, and HSV-2 gD.^{256,377,573} Recent biochemical and proteomics studies have advanced the understanding of interactions between viral proteins and with host cell proteins^{592,629} and will help to guide new analyses of the molecular mechanisms of VZV replication. Many aspects of VZV–host interactions require further study, such as how the virus takes over host T cells to cause viremia and how VZV reactivates from latency in neurons. While the introduction of antiviral drugs and vaccines to treat and prevent varicella and zoster represent major clinical achievements in VZV control, further insight into VZV replication, the functions of specific viral genes in subtypes of host cells, and viral immune evasion strategies using new tools promises to provide further progress in preventing VZV

morbidity and mortality in healthy populations and safer vaccines for high-risk patients.

HISTORY

Human herpesvirus 6 (HHV-6) was discovered in 1986 in patients with lymphoproliferative disorders.²³³ Initially named human B-lymphotropic virus, it was later found mainly to infect and replicate in lymphocytes of the T-cell lineage. HHV-6 isolates are classified into two closely related groups that have been termed variants A (HHV-6A) and B (HHV-6B), and are now recognized as distinct herpesvirus species. HHV-6B is the major causative agent of exanthem subitum (ES),³⁰⁶ but no disease has been clearly associated with HHV-6A.

Human herpesvirus 7 (HHV-7) was isolated in 1990 from a healthy individual whose cells were stimulated with antibody against CD3 and then incubated with interleukin-2 (IL-2).⁹³ The virus is one of the causative agents of ES²⁶⁸ and has been associated with febrile convulsions in young children.²⁹⁸ HHV-6 and HHV-7 are ubiquitous, with more than 85% of adults having antibody to both viruses.

INFECTIOUS AGENT

Classification

Human herpesviruses 6A, 6B, and 7 share many properties with other herpesviruses, including virion structure, many features of genomic and genetic architecture, high prevalence in their natural host, and the ability to establish latent infections in the host. The lytic replication cycle (Fig. 64.1) is generally similar to that for other herpesviruses. These viruses belong to the *Roseolovirus* genus of the betaherpesvirus subfamily, and are characterized by growth in T lymphocytes (although they can also infect other cell types), high prevalence, and association with febrile rash illness. As betaherpesviruses, roseoloviruses are related to cytomegaloviruses (CMV), including having genetically colinear genomes, encoding several subfamily-specific genes, and having protracted replication cycles. In addition to the human roseoloviruses, a virus closely related to HHV-6A and HHV-6B has been identified in chimpanzees¹⁵⁶; a somewhat more distantly related virus has been identified in mandrills.¹⁵⁵

HHV-6A and HHV-6B are closely related, yet molecularly and biologically distinct, viruses (eFig. 64.1) that differ with respect to their cell tropisms, interactions with cells and signaling pathways of the immune system, DNA sequences, and epidemiology.^{1,34,78,126}

Propagation and *In Vitro* Cell Tropism

Human herpesviruses 6A and 6B infect a variety of cultured human cells, such as T cells (preferentially mature CD4+), natural killer (NK) cells, $\gamma\delta$ T lymphocytes, primary fetal astrocytes and dendritic cells, olfactory-ensheathing cells (HHV-6A but not HHV-6B), and peripheral blood mononuclear cells (PBMC). Fresh isolates can be adapted to grow in continuous T-cell lines, such as HSB-2 and J JHAN for HHV-6A, and Molt-3 and MT-4 for HHV-6B. Cell lines derived from megakaryocytes and glioblastomas—as well as neural, epithelial, and fibroblastic cells—can also support limited HHV-6 replication.^{34,69}

HHV-6A has a greater capacity than HHV-6B for replication in cultured cells of neuronal origin.⁷⁰ In primary astrocytes, HHV-6A establishes a productive lytic infection, whereas HHV-6B produces little cytopathic effect and only small amounts of viral nucleic acids, proteins, or infectious progeny, and establishes a long-term, low-level persistent infection.⁷⁹ In an oligodendrocyte cell line, over the course of 30 days HHV-6A transitioned from a lytic state to a quiescent infection that may represent latency (reactivation was not demonstrated), whereas HHV-6B infection was nonproductive and

FIGURE 64.1. Stages of replication. The replication scheme is based on published data from refs.^{27,80,170,250,257} A single receptor is shown, although it is likely that the virus employs multiple receptors to enable entry into a wide range of cell types. AL, annulate lamellae; G, Golgi complex; HS, heparan sulfate; Nu, nucleus; NM, nuclear membrane; R, receptor (CD46 for HHV-6A and HHV-6B, CD4 for HHV-7); V, vacuole, MVB (multivesicular body).

did not persist.⁷ In some cell types, the HHV-6 genome integrates into a host-cell telomere (chromosomally integrated, or ciHHV-6), establishing a quiescent form of persistence that may represent a form of latency.¹⁶

In contrast, HHV-7 has a narrow *in vitro* cell tropism, thus far being restricted to primary phytohemagglutinin (PHA)-stimulated CD4⁺ T cells obtained from umbilical cords or PBMC, and an immature continuous T-lymphoblastoid cell line, SupT-1.²⁸ HHV-6 and HHV-7 induce similar cytopathic effects, characterized by ballooning refractile cells (Fig. 64.2).

Virion Structure

Roseoloviruses share the standard features of herpesvirus virions: an icosahedral capsid 90 to 110 nm in diameter that contains the 145- (HHV-7) and up to 170-kb (HHV-6) double-stranded DNA (dsDNA) genome, a tegument that surrounds the capsid, and a lipid bilayer envelope studded with virus-specified membrane proteins and glycoproteins. Enveloped extracellular virions are 160 to 200 nm in diameter^{24,25,144,312} (Fig. 64.3). By thin-section electron microscopy (EM), HHV-6 teguments are smooth and fill the space between the capsid and envelope,

whereas the HHV-7 tegument has an electron lucent space between the tegument and envelope.^{25,144} Immunoelectron microscopy with a monoclonal antibody (mAb) against a tegument protein encoded by the HHV-7 *UI4* gene showed reactivity primarily at the outer periphery of the tegument.²⁵³ Virions consist of at least 29 polypeptides, including 6 in the envelope fraction and cellular p53.^{34,265} There are at least three distinct sets of glycoproteins: gp105k and gp82k; gp116k, gp64k, and gp54k; and gp102k.

Genome Structure and Organization

Genomic Architecture

As packaged in nucleocapsids, roseolovirus genomes are composed of a central unique segment (U) bracketed by a pair of direct repeat structures, DRL and DRR (Fig. 64.4; eFig. 64.2; Table 64.1).^{78,163,176} Some forms of HHV-6 intracellular replicative intermediates do not have duplicated DR segments; the unit form of these concatemeric or circular genomes consists of one copy of the U segment and a single DR.³¹ From left to right, HHV-6 DRs consist of 25 to 29 base pairs (bp) of unique sequence, a conserved *pac1* (cleavage and packaging) element,

FIGURE 64.2. Cytopathic effect by HHV-6B. **A:** Balloon-like cells surround clumps of lymphocytes with positive staining by immunofluorescence antibody (IFA). **B:** Balloon-like cells stained by IFA using convalescent serum from a patient with exanthem subitum. Similar cytopathic effects and staining are seen for HHV-6A, HHV-6B, and HHV-7.

an array of heterogeneous long terminal repeats (LTR) based on the sequence TA(A/G)(C/G)(C/T)C that span about 300 bp in laboratory-passaged strains and up to 3 kb in low-passage viruses, about 7 kb of unique sequence that encodes a handful of genes, an array of sequences similar to those present at the telomeres of mammalian chromosomes (R-TRS, [TAACCC]_n), a

conserved pac2 element, and 16 to 18 bp of unique sequence (eFig. 64.3). The length of the telomeric sequence can vary from isolate to isolate and is stable during serial passage and over time in humans.³ The HHV-7 R-TRS is more heterogeneous than for HHV-6 (eFig. 64.3).²²⁷ Despite the differences, HHV-7 cleavage and packaging signals are recognized and

FIGURE 64.4. HHV-6B genomic and genetic architecture. The diagram is based on annotations of published genomic sequences.^{78,85,147,158} The positions and arrangements of the major internal repeat elements, the origin of replication (*oriLyf*), and the structure of the direct repeat (*DR*) termini are shown for frame (ORF) sizes, orientation, and locations are indicated. ORF found in HHV-6B and not in HHV-6A are designated B1 through B9. The orientation and order of the six conserved herpesvirus core gene blocks are indicated, as is the block (U2 to U19) found only in betaherpesviruses.

processed during HHV-6 infections, and vice versa.²²⁷ Other repeat arrays (R0 to R3) are located in the U segment of each of the viruses^{78,101,126,180,198} (Table 64.1 and Fig. 64.3). Compared with other herpesviruses, roseoloviruses have relatively low G+C content (Table 64.1).

The function of the mammalian telomere-like sequences is not fully understood. They appear to have no role in nuclear

retention of viral DNA, efficiency of DNA replication, or packaging-associated DNA cleavage.^{35,73} Given the necessity of similar sequences for integration of Marek's disease virus genomes into telomeres of its host cells,¹³⁵ it had been suspected that these sequences are involved in site-specific integrations of HHV-6 genomes that have been observed in the vicinity of host chromosome telomeres (ciHHV-6).^{65,284} In the instance that was mapped to the sequence level,¹⁶ the virus genome is integrated into the host chromosome such that a TRS array is present at the tip of the chromosome, followed by an intact virus genome in the prototypical DRL to DRR orientation, followed by another TRS array, a subtelomeric region, and then the unique sequence of the chromosome that harbors the virus (Fig. 64.5). Thus far, 8 chromosomes have been identified as targets for HHV-6 integration.¹⁹⁴ For most individuals with germline ciHHV-6, a single chromosome is targeted; several instances have been identified in which an individual inherited ciHHV-6 on one chromosome from one parent and on a different chromosome from the other parent. Although HHV-7 also has telomere-like sequences, it has not been observed to integrate into host chromosomes.

Genetic Structure and Genetic Relationships

Protein-encoding open reading frames (ORF) are encoded on both strands of the genome, with little overlap among adjacent

ORF (Fig. 64.4 and eFig. 64.2). The HHV-7 genome is more compactly arranged than that of HHV-6, with a similar genetic complement being encoded in a U segment that is 12 kb shorter than for HHV-6 (Table 64.1). In addition to the repeat arrays, two genomic regions have no obvious protein coding capacity: the region between U41 and U42 that harbors the origin of lytic DNA replication (oriLyt), and the region between U77 and U79.

Many of the genes encoded in the central portion of roseolovirus genomes are conserved among the alpha-, beta-, and gammaherpesviruses^{78,101,180,198} (Table 64.2; Fig. 64.4; eFig. 64.2; and Chapter 59). A betaherpesvirus-specific gene cluster is located to the left of the core genes. Clusters of genes unique to roseoloviruses flank the core genes.

Over the conserved domains, roseoloviruses are genetically colinear with cytomegaloviruses, although the cytomegaloviruses encode many genes with no roseolovirus counterpart. Between HHV-6 and HHV-7, amino acid sequence identities range from 22% to 75%, most being approximately 50%. HHV-6A and HHV-6B have overall nucleotide sequence identity of 90%; the portions of the genomes that span U32 to U77 are highly conserved (95% identity), whereas the segment spanning U86 to U100 is only 72% identical.⁷⁸

Intraspecies sequence variation is very low. Across segments spanning several kilobases, HHV-6A strains differ by less than 0.5%, although there are short segments of greater variability.³⁴ HHV-6B strains HST and Z29 differ by less than 1% across their entire genomes. Length differences in the telomere-like sequence can be used for strain tracking.³ Other than repeat copy number differences, HHV-7 strains JI and RK differ by only 179 bp (0.1%) over their genomes. Conservation can be even higher at the amino acid sequence level.^{90,221} Subgroups of HHV-6B and HHV-7 isolates have been identified at some genomic loci.^{54,90}

Roseoloviruses differ somewhat from each other in their genetic complement. Nine HHV-6A ORFs do not have HHV-6B counterparts, and nine HHV-6B ORFs have no HHV-6A counterpart.⁷⁸ Interpretation of these differences is difficult because somewhat different criteria have been employed to predict functional ORF of the sequenced viruses. In addition, in the absence of clear similarity with genes from other herpesviruses or in the sequence repositories, such predictions must be considered provisional pending experimental study. Of six B variant-specific genes analyzed, transcripts were detected across all six, with three (B3, B6, and B7) being expressed as immediate early (IE) genes.²¹⁰ Thus, at least some of the variant-specific genes are functional.

DR3, U6, U22, U83, and U94 are encoded by HHV-6A and HHV-6B, but not HHV-7. U94 is a homolog of the

parvovirus ns1/rep gene. A related protein is encoded adjacent to a U95 homolog in rat CMV; however, in addition to not being encoded by HHV-7, neither human nor murine CMV encode a U94 homolog.²⁹¹ HHV-7 encodes a duplicated gene (U55A and U55B) that is encoded as a single copy by HHV-6A and HHV-6B. Genes unique to roseoloviruses include U20, U21, U23, U24, U24A, U26, and U100.

Although no amino acid sequence similarity has been identified, the general layout and splicing patterns of two human cytomegalovirus (HCMV) immediate-early (IE) regions are conserved in the roseoloviruses. Thus the roseolovirus IE-B domain that spans U17 to U19 corresponds to the HCMV UL36 to U38 IE locus, and the IE-A domain spanning U86 to U90 corresponds to the HCMV major IE locus.^{175,198} Every betaherpesvirus encodes several members of a family of duplicated and diverged genes that are related to HCMV US22 and are referred to as the US22 gene family.¹⁹⁸ For HCMV, some US22 family members are transcribed as IE genes and encode transactivating functions. In the roseoloviruses, DR2, DR6/7, U2, U3, U5, U7 (U5/7 in HHV-7), U8, U17/16, U25, and U95 are all members of this gene family. At least four of the HHV-6A US22 homologs encode transcriptional transactivators (DR6, U3, U16, and U25).

HHV-6 has been subject to little direct genetic experimentation. Kondo et al.¹⁵⁰ were able to replace the HHV-6B U3-U7 gene cluster with a selection marker, demonstrating that these genes are not essential for virus replication or latency in cultured cells. HHV-6A genomes have been cloned as bacterial artificial chromosomes (BACs) in three laboratories. One of the BACs is capable of regenerating infectious virus after transfection into susceptible human cells, and has been used to identify glycoprotein Q1 (gQ1) as an essential protein.²⁷³ The other two BACs expressed some viral genes and could be maintained in transfected cells under antibiotic selection, but did not produce infectious virions.^{16,31}

Stages of Replication

Entry

A cellular receptor for HHV-6,²³⁵ CD46, is also a member of the regulator of complement fixation family and is expressed on the surface of all nucleated human cells; it is also a cellular receptor for measles virus. Evidence for the CD46 receptor activity includes (a) downmodulation of CD46 expression in activated primary human CD4+ lymphocytes infected with HHV-6A or HHV-6B; (b) inhibition of HHV-6 infection and associated cell fusion by mAb against CD46 and by soluble CD46; and (c) nonhuman cells being rendered susceptible to HHV-6-mediated membrane fusion and HHV-6 entry by expression of CD46 (reviewed in 274). The short consensus repeats 2 and

HHV, human herpesvirus; HCMV, human cytomegalovirus; ORF, open reading frame; IE, immediate early.

3 of the CD46 ectodomain are required for HHV-6 receptor activity.¹⁰⁵ HHV-6A can mediate fusion from without (FFWO; fusion that does not require viral protein synthesis) in a variety of human cells,¹⁹¹ an activity that is dependent on CD46 expression. HHV-6B strain HST does not mediate FFWO but strain PL-1 can.²¹³ mAb against gB and gH inhibit HHV-6 infection and FFWO,¹⁹¹ demonstrating that gH and gB are critical for virus entry and probably have fusogenic activity. HHV-7, but not HHV-6, uses CD4 as a receptor, although the virus can infect cells that do not express detectable CD4.²⁸

The human immunodeficiency virus type 1 (HIV-1) co-receptors, CXCR4 and CCR5, have been studied to determine whether they serve similar functions for the roseoloviruses. Cells from individuals lacking CCR5 were able to support growth of all three viruses, and these individuals were seropositive for the viruses, indicating that this molecule is not essential for viral replication.³⁰⁸ Data for CXCR4 are conflicting. An mAb against CXCR4 did not inhibit infection by any of the viruses,^{244,308,325} nor did a specific CXCR4 antagonist that can inhibit HIV-1 infectivity.³²⁵ Nonetheless, the natural CXCR4 ligand, SDF-1 α , inhibited HHV-7 infection at 2.5 mg/mL²⁴⁴ but not at 1.0 mg/mL.³²⁵

On the virus side, two HHV-7 glycoproteins have been identified as being able to bind cell surface proteoglycans heparan and heparan sulfate: gB, and the spliced glycoprotein encoded by U100.^{218,243,248} Other virion proteins are likely involved in receptor interactions or entry, such as the gH-gL complex, which along with products of U100, are targets for complement-independent neutralization.^{34,69} gQ1, a spliced product of the U97, U98, U99 and U100 ORFs, is unique to roseoloviruses.²⁷⁴ The gene is expressed via complex splicing, producing a number of envelope-associated polypeptides. The HHV-6 gH-gL complex associates with the 80-kd virion envelope form of gQ1 (gQ-80K; gQ1). A different small transcript from *U97* gene encodes an unrelated protein of 37 kd (gQ-37K; gQ2) that interacts with the gH/gL/gQ1 complex in infected cells and virions.⁸ Interaction of the virion with the CD46 receptor is via the gH/gL/gQ1/gQ2 complex (Fig. 64.6).^{8,193,234}

HHV-6A strains GA and U1102, and HHV-6B strain PL-1, bind CD46; HHV-6B strain HST does not. HHV-6 U47 is a positional homolog of the HCMV glycoprotein O (gO) gene. U47 encodes a component of a different envelope complex that also includes gH/gL, but is not a CD46 ligand and likely plays a different role from gH/gL/gQ1/gQ2.¹⁸⁸ gQ and gO have much greater sequence divergence between HHV-6A and HHV-6B than do other glycoproteins (76.8% and 72.1% identity, respectively), suggesting that they contribute to the biologic differences between these viruses. Lipid rafts are critical for HHV-6 entry. Depletion of cholesterol from virion and cell membranes inhibits virus infection,¹¹⁸ and HHV-6A binding to cells triggers rapid redistribution of CD46 to lipid rafts.^{190,272} Envelope glycoproteins are enriched in raft fractions and raft components are incorporated into virions.¹³⁶

Transcription

Herpesvirus genes generally belong to one of two main categories: latent or lytic. There are three general kinetic classes of

FIGURE 64.6. Virion-receptor interactions.

lytic genes: immediate early (IE) genes that provide functions for regulation of gene expression, early (E) genes that encode proteins needed for DNA replication, and late (L) genes that encode virion proteins.

Roseolovirus gene expression follows the general program of other herpesviruses. For HHV-6B, 8 genes are expressed as IE, 44 as early, 44 as late, and 4 were biphasic²⁸⁶ (Table 64.2). For HHV-6A and HHV-6B, U83 and U89/90 encode experimentally proven IE genes (expression not dependent on *de novo* protein synthesis).^{91,127,221,236} For both loci, multiple differently regulated transcripts are expressed (eFig. 64.4). The IE transcript of U83 is spliced and expresses a truncated version of the chemokine encoded by U83, whereas the full-length transcript is expressed as a late gene.^{91,328} U42 encodes a homolog of the HSV IE gene $\alpha 27$ and HCMV UL69, which is regulated as an E gene; HHV-6B U42 is not transcribed in the absence of *de novo* protein synthesis; thus, its regulation is similar to that of its HCMV counterpart.²²¹ Expression of the U90 IE gene rose to more than 10 copies per cell within 8 hours, whereas a structural gene transcript (U11) took 16 hours to reach comparable levels²²¹. At 72 hours after infection, U11 was expressed at several hundred copies per cell. Transcripts of the gene needed for initiation of DNA replication (U73) and the parvovirus ns1/rep homolog (U94) were expressed at much lower levels (<10 copies/cell).

Most transcripts expressed by these viruses are not likely to be spliced, although several are, some more than once.^{219,248} In addition, the use of some splice sites is kinetically regulated^{181,186,236,328}; others use noncanonical donor and acceptor sequences.^{91,328} Megaw et al.¹⁸⁰ provided detailed predictions of splicing patterns.

The HHV-6 R3 repeat element (R2 in HHV-7) is a potential IE enhancer. R3 is located about 300 bp upstream of the oppositely oriented U89/90 and U95 genes; it is present in more than 25 copies per genome (Table 64.1) and contains potential transcription factor-binding sites (nuclear factor- κ B [NF- κ B] and AP2 in HHV-6A; PEA3 and AP2 in HHV-6B; and PEA3 in HHV-7). U95 has amino acid sequence similarity with the murine CMV (MCMV) IE2 gene and is a member of the HCMV US22 gene family. Deletion of three R3 units decreases promoter activity 15-fold, and NF- κ B family members p50 and c-Rel bind to NF- κ B sites in R3.²⁶⁷ The HHV-6 major immediate early gene (U90–89) promoter (MIEp) is highly active in T cells; its activity is reduced in the absence of intron 1. The NF- κ B-binding site in the R3 repeat is critical for this activity.¹⁷⁷

Promoters of the genes encoding the HHV-6A DNA polymerase (U38) and its processivity factor (U27) were active in infected, but not in uninfected, cells; thus, they have virally responsive elements. The U38 promoter is TATA-less, and its activity is dependent on a palindromic activating transcription factor (ATF)/CREB-binding site.⁵

Four latency-associated transcripts from the IE1/IE2 locus are oriented in the same direction as the IE1/IE2 genes and share their protein-coding regions with IE1/IE2, but have latency-specific transcription initiation sites and exons.¹⁵¹ In addition, transcripts from the U94 gene have been detected in primary PBMC that were polymerase chain reaction (PCR)-positive for HHV-6 DNA, and negative for other lytic gene transcripts.²²⁹ If a role for U94 in HHV-6 latency is identified, this would constitute a significant biologic difference from HHV-7 because

HHV-7 does not encode a U94 homolog. Hints to U94 function may come from studies of rat CMV, which encodes a U94 homolog that binds single- and dsDNA and is not essential for virus replication.²⁸⁹

Translation and Transport

HHV-6 U94 is expressed as a low copy number-spliced transcript that encodes several small AUG-initiated ORF upstream of the U94 ORF.²²¹ None of the initiation codons, including that for U94, has the hallmarks of being efficiently translated. This suggests that in addition to tight control of its transcription, U94 is translationally regulated to prevent high expression.

HHV-6 U51 encodes a G protein-coupled receptor homolog that is expressed on the surfaces of transfected T-cell lines but in other cell lines accumulates intracellularly without being transported to the cell surface,¹⁸² suggesting the presence of a cell-specific transport or processing function.

Virally Encoded Transcription Regulators

Roseoloviruses encode genes that regulate transcription of viral and cellular genes. The regulators that have been studied are encoded by the HHV-6A IE-A and IE-B loci, DR6, U3, U27, and U94. Positive regulatory effects have been seen by transfection or infection in a variety of cell types on heterologous viral promoters, including the HIV-1 and human T-cell lymphoma 1 (HTLV-1) LTR, Epstein-Barr virus latent membrane protein 1 (LMP-1) and Epstein-Barr virus nuclear antigen 2 (EBNA-2), HSV gD, human papillomaviruses 16 and 18, and the adenovirus E3 and E4 genes.^{34,178,192} In addition, negative regulatory effects have been observed on cellular promoters for p53, H-ras, and CXCR4,^{14,133,308} along with mixed effects on the CD4 promoter (positive by HHV-6A and negative by HHV-7).^{87,241} Upregulation of the HIV-1 LTR is variously dependent on the presence of the NF- κ B, AP-1, trans-acting response (TAR), and SP1 sites, whereas its suppression by U94 is independent of NF- κ B and SP1 but dependent on the TAR element.

Functions of Immediate Early Gene Products

HHV-6 IE-A consists of two genetic units, IE1 and IE2, corresponding to U90 to U89 and U90 to U86/87, respectively.²¹² IE2 proteins with molecular masses of 100, 85, and 55 kd are detectable 3 days after infection, whereas IE1 proteins of >170 kd are detectable within 8 hours.²¹² IE2 is expressed via differential splicing and alternative translation initiation. IE2 proteins show a mixed cytoplasmic and nuclear localization pattern. At earlier times (8 to 48 hours after infection), it is present as intranuclear granules, whereas at later time points (72 to 120 hours after infection), IE2 coalesces into a few large immunoreactive patches. IE2 can induce the transcription of a complex promoter, such as the HIV-LTR, as well as simpler promoters, whose expression is driven by a unique set of responsive elements (*cis*-acting replication element [CRE], nuclear factor of activated T cells [NFAT], NF- κ B).¹⁰⁴ Moreover, minimal promoters having a single TATA box or no defined eukaryotic regulatory elements can be activated by IE2, suggesting that it plays an important role in initiating the expression of several HHV-6 genes as a promiscuous transactivator.²⁸² HHV-6 IE2 interacts with the heterogeneous nuclear ribonucleoprotein K (hnRNP K) and the beta subunit of casein kinase 2 (CK2 β).¹⁸⁹ Although IE2 interacts with Ubc9, the protein responsible for conjugation of Sumo to target protein, IE2 does not undergo sumoylation,

and the interaction negatively affects its transactivator function.²⁸³ U95 interacts with the mitochondrial GRIM-19 protein that promotes cell death induced by IFN- β and retinoic acid.³¹¹ Short-term HHV-6B infection of MT-4 T-lymphocytic cells induced syncytial formation, resulted in decreased mitochondrial membrane potential, and led to progressively pronounced ultrastructural changes, such as mitochondrial swelling, myelin-like figures, and a loss of cristae. The high affinity between U95 and GRIM-19 may be closely linked to the detrimental effect of HHV-6B infection on mitochondria.

HHV-6 IE1 stably interacts with PML-bodies [also known as ND10 or nuclear promyelocytic leukemia protein (PML) oncogenic domains (POD)].²⁵¹ Remarkably, PML bodies remain structurally intact and associate with the IE1 protein throughout lytic HHV-6 infection, unlike other herpesviruses, which trigger PML-body dispersal. IE1 is covalently modified by conjugation to the small ubiquitin-like protein, SUMO-1,²⁵¹ which does not influence POD targeting.¹⁰³

HHV-6 U16 is in the IE-B region of the genome. The protein-coding region of one transcript is generated by an in-frame splicing of ORF U17 and U16, and another includes ORFs U16 and U15. A third differentially spliced complementary DNA (cDNA) (U16+) was identified by 5' rapid amplification of cDNA ends. These transcripts arise from at least two transcription initiation sites; the U17/U16 spliced transcript is expressed under IE conditions, and a multiply spliced gene product encoded by U16 is expressed as a late gene. The U17/U16 and the U16+ gene products can transactivate the HIV LTR.⁸⁹

Functions of Other Virally Encoded Gene Products

The U3 to U7 gene cluster is not essential for virus replication or latency in cultured cells.¹⁵⁰

ORF U11 encodes p100 and 101K, the HHV-6A and HHV-6B homologs of HCMV pp150.^{197,216} The protein is a tegument protein and is the dominant antigen recognized by HHV-6-specific IgG in immunoblots. The HHV-7 U11-encoded counterpart, p86, is one of the major HHV-7 antigens.²⁵² HHV-7 U14 encodes pp85, an 85-kD, tegument-associated phosphoprotein that is also a major antigen.²⁵²

gB (encoded by U39) is a conserved herpesvirus glycoprotein that is found on virions of most herpesviruses, including roseoloviruses. It has roles in attachment and penetration and is a target for complement-independent neutralization. The primary HHV-6A gB translation product of about 112 kD is proteolytically cleaved to form disulfide-bond-linked subunits of 64 kD and 58 kD; for HHV-6B and HHV-7, the corresponding products were approximately 102, 59, and 50 kD; and 112, 63, and 51 kD, respectively. As with the gB of other herpesviruses, the extracellular domain of HHV-7 gB binds to cell-surface heparan sulfate proteoglycans, indicating a role in adsorption of the virion to cells.²⁴³

HHV-6 U42 is a homolog of HCMV UL69. Like pUL69, pU42 homodimerizes and shuttles from between the nucleus and cytoplasm, but pU42 does not interact with the cellular DExD/H-box helicases UAP56 and URH49, and thus does not export mRNA.³²⁷

As for other herpesviruses, the conserved virion glycoproteins gH and gL (encoded by ORFs U48 and U82, respectively), heterodimerize and together have roles in membrane fusion associated with both virus entry and cell-to-cell spread.²⁷⁴

As mentioned, the HHV-6 gH–gL complex forms independent envelope complexes with either gQ1/gQ2 or gO.^{42,188} gQ1 is essential for HHV-6A replication.²⁷³

The proteinase required for capsid maturation, DNA packaging, and virus assembly is encoded by U53. The HHV-6 proteinase, like its homologs in other herpesviruses, is translated as a precursor molecule that is autolytically processed at two sites (the release and maturation sites) to produce the mature proteinase and assembly proteins. As in the other herpesviruses, the processing sites consist of an Ala-Ser sequence. In contrast to the other herpesviruses, roseoloviruses lack an internal autocatalytic cleavage site (Ala-Ala instead of Ala-Ser), which results in their proteinase being a single-chain enzyme.²⁷⁹

The HHV-6 U69 gene product (pU69) is the presumed functional homolog of HCMV UL97-encoded kinase (pUL97), which converts ganciclovir to its monophosphate metabolite in HCMV-infected cells.^{12,68,174,231} The efficiency of ganciclovir phosphorylation in HHV-6-infected cells, and by vaccinia virus-expressed pU69, however, is relatively poor.

Viral DNA replication was reduced 50-fold, and cytopathic effects were also inhibited in T cells stably expressing short interfering RNA (siRNA) specific for the HHV-6 G-protein-coupled receptor (GPCR) homolog encoded by U51, suggesting that HHV-6 U51 is a positive regulator of virus replication.³²⁶

The U94 genes of HHV-6A and HHV-6B encode homologs of the parvovirus ns1 or rep gene, which is essential for parvovirus DNA replication (see Chapter 57). The Rep68 protein of adeno-associated virus type 2 (AAV-2) is a site-specific adenosine triphosphate-dependent endonuclease and helicase, involved in site-specific integration of the viral genome into the host genome. HHV-6A U94 can serve as a helper for AAV-2 replication, and U94 can complement a point mutant of AAV-2 rep.²⁷⁸ As mentioned, U94 transcripts have been detected in PBMC during latency,²²⁹ and HHV-7 does not encode a U94 homolog, although rat CMV does. Activities associated with U94 include suppression of H-ras and bovine papillomavirus 1 (BPV-1) transformation and transcription from the H-ras and HIV-1 LTR promoters¹⁵; the ability to bind to single-strand DNA (ssDNA)⁷⁷ and to human TATA-binding protein¹⁸⁹; and the ability to inhibit the replication of HHV-6 and other betaherpesviruses (HHV-7 and HCMV), but not HSV.^{42,229} This confirms the activity of U94 in the regulation of HHV-6 replication and has implications for co-reactivations and latency of human betaherpesviruses.⁴² In addition, expression of U94 in cultured endothelial cells inhibits the formation of capillary-like structures, reduces cell migration, and blocks angiogenesis.⁴⁰

Direct repeat 6 (DR6) is a nuclear protein that interacts with the U27-encoded viral DNA polymerase processivity factor, p41.²³⁷ HHV-6A lineages that spontaneously lost the genomic segment spanning DR1 through the first exon of DR6 appear to have a growth advantage in at least some cell lines.³³

Replication of Genome

NUCLEOTIDE METABOLISM

Roseoloviruses encode several enzymes that have roles in nucleotide metabolism and provide the precursors needed for nucleic acid synthesis: ribonucleotide reductase, a phosphotransferase, alkaline exonuclease, and uracil-DNA glycosylase, but do not encode a thymidylate synthase or thymidine kinase.

Roseolovirus ribonucleotide reductases consist of a single subunit homologous to the large subunit of two-subunit enzymes.

INITIATION AND ELONGATION

For HHV-6 and HHV-7, lytic DNA replication is initiated at an oriLyt that is similar to alphaherpesvirus oriLyts and markedly different from the oriLyts of CMV and gammaherpesviruses.^{123,154,227,290} The oriLyts are located between the 5' end of U41 and the 3' end of U42. The minimal oriLyt segment is about 300 bp long, and a fully functional oriLyt is about 800 bp long. Multiple tandem iterations of the origin sequence enable more efficient replication of plasmids in transient replication assays, and confer a replication advantage on virus genomes.⁷⁵ A critical element near the center of oriLyt consists of two palindromically arranged sequences, OBP-1 and OBP-2, that are recognized by the origin-binding protein (OBP) encoded in roseoloviruses by U73 (a homolog of HSV-1 UL9). The core OBP sites flank an AT-rich sequence of about 30 bp (eFig. 64.5). Several positions within the OBP binding sites are conserved among the viruses that encode OBP homologs, whereas others differ in a manner that provides viral specificity. Replication efficiency is also affected by the sequence and composition of the AT-rich spacer. HHV-6A and HHV-6B are able to support replication of each other's oriLyt. Plasmids containing the HHV-6 oriLyt, however, were replicated in HHV-7-infected cells, but not vice versa, suggesting that oriLyt sequences and binding specificities differ between the viruses. It is thus surprising that the HHV-6 OBP binds strongly to the HHV-7 OBP binding sites, but the HHV-7 OBP binds strongly to only one of the HHV-6 OBP sites.¹⁵³

In addition to OBP, roseoloviruses encode homologs of the six other virally encoded proteins needed for replication of plasmids containing an HSV oriLyt. They include the major DNA-binding protein, the DNA polymerase and its processivity factor, and three gene products that comprise the helicase–primase complex. In an *in vitro* DNA synthesis system that employed the single-stranded M13 genome as a template, the HHV-6A DNA polymerase alone synthesized molecules shorter than 100 nucleotides.¹⁶² Addition of the polymerase processivity factor homolog encoded by U27 (p41), led to synthesis of molecules >7,200 nucleotides in length, similar to the processivity increase produced by its homologs in other herpesviruses. The N-terminal portion of the processivity factor was required for this activity.

GENOME PACKAGING AND CLEAVAGE

About 5% of genomes contained in nucleocapsids are circularized, creating a juxtaposition of direct repeat right (DRR) and direct repeat left (DRL) that results in assembly of a complete cleavage and packaging signal. The structure of such circular genomes is as follows: DRR-(terminal resolution site [TRS])n-pac2-N16–18-junction-N25–29-pac1-het(TRS)n-DRL.^{73,78,100,227,242,277} Some heterogeneity is seen in the sequences of concatemeric junctions, with 1 to 8 bp of additional, possibly untemplated, DNA being inserted into some molecules.^{78,242} Circularized molecules provide the template for rolling-circle replication, which leads to production of concatemers of nascent DNA suitable for packaging into capsids.²²⁷ In the model of Frenkel and Roffman,⁹² concatemers are cleaved between properly juxtaposed pac1 and pac2 sequences after a headful threshold has been reached during packaging, leading to

unit-length packaged genomes. Relatively few multimeric concatemers are generated during replication, and compared with HSV, HHV-6 replication intermediates are not highly branched, suggesting less frequent homologous recombination among replicating molecules.²⁴⁵ The genome of an HHV-6A BAC that is unable to replicate as an infectious virus has a single DR and is hypothesized to represent a replication intermediate,³¹ but it has not been determined how a mature genome flanked by DR elements could be generated from such a structure.

Identification of the oriLyt and cleavage and packaging signals allowed development of amplicon systems based on HHV-6 and HHV-7^{32,73} that feature T-cell replication, oriLyt, and cleavage-packaging signals, and can be used for expression of foreign genes. They have potential use as gene therapy vectors.

ASSEMBLY AND RELEASE

Roseolovirus virion maturation and egress appear to involve a process of successive envelopment, deenvelopment, and reenvelopment steps as the virion moves from one membrane-bounded compartment to another (Fig. 1). DNA replication and capsid assembly take place in the nucleus; nascent capsids that contain DNA appear about 3 days after infection.^{25,29} A feature that is likely to be a result of the envelopment-development process is the presence of abundant nonenveloped, tegumented nucleocapsids in the cytoplasm. In some studies, particles with neither tegument nor envelope were observed in the cytoplasm^{25,285}; teguments appeared to be acquired cytoplasmically in pools of electron-dense material. Membrane-bound nuclear structures (tegusomes) have been proposed as a site of tegument acquisition,²²⁶ but given the relatively low frequency with which they are observed, this is not the major pathway. Because viral glycoproteins gB, gH-gL, and gQ1 are absent from the plasma membrane, envelopment or egress by budding directly from the cytoplasm are not likely. These glycoproteins are concentrated in cytoplasmic structures known as annulate lamellae,^{37,55,285} which may correspond to the endosome- and TGN-related intracellular membranes where final envelopment of virions occurs.¹⁹⁰ HHV-6 virions collect in multivesicular bodies (MVB) that contain numerous mature virions and small exosomal vesicles.¹⁹⁰ MVB membranes can fuse with the plasma membrane, resulting in release of mature virions and the exosomal particles. In addition to exocytosis, mature virions can be released by cell lysis.^{55,285}

Fate of Host Cell

Roseolovirus infection has profound effects on host cells, including margination of chromatin, shut-off of host-cell DNA synthesis, generalized stimulation of host-cell protein synthesis, and development of the classic cytopathic effect of ballooning, refractile, multinucleated giant cells, as has been reviewed elsewhere.^{34,69} For at least HHV-7, the multinucleated cells develop, not by fusion of cells into syncytia, but by polyploidization that is linked to dysregulation of cdc2 and cyclin B. This leads to an accumulation of cells in the G2 to M phase of the cell cycle, with nuclei continuing to reproduce in the absence of cell division.²³⁸ Cytokines can be induced, including interferon- α (IFN- α), interleukin-1 β (IL- β by HHV-6A but not HHV-6B), and tumor necrosis factor (TNF), as well as the G-protein-coupled peptide receptor, EB1. In addition, HHV-6A and HHV-6B can inhibit the proliferative responses of PBMC to antigens and mitogens.³⁴

HHV-6A infection induces cell-surface expression of CD4, which then renders NK cells susceptible to HIV-1 infection. HHV-6A, but neither HHV-6B nor HHV-7, downregulates cell-surface expression of CD3; HHV-7 sharply downregulates CD4.^{28,34}

Downregulation of expression of the HIV-1 co-receptor CXCR4 and a coupled reduction in Ca^{2+} flux in response to SDF-1 α was observed in two studies^{244,308}; in contrast, no effect of HHV-7 infection on CXCR4 expression was seen in another study.³²⁵ HHV-6 affects HIV-1 infection in a co-receptor-dependent manner, suppressing CCR5-tropic but not CXCR4-tropic HIV-1 replication in human lymphoid tissue *ex vivo*, apparently via induction of the CCR5 ligand regulated on activation normal T cells expressed and secreted (RANTES), the most potent HIV-inhibitory CC chemokine. Exogenous RANTES mimics the effects of HHV-6 on HIV-1.¹⁰⁷ HHV-6 infection induces *de novo* synthesis of RANTES in primary human endothelial cell cultures,⁴¹ the highest induction being in microvascular endothelial cells that have very low susceptibility to HHV-6 infection.

HHV-6A infection induces a p53-independent G2 cell cycle arrest in human cord blood mononuclear cells²¹¹; newly synthesized viral proteins are necessary for this.⁶⁷ HHV-6B infections of T-cell lines led to G1/S and G2/M arrests concomitant with an increased level and enhanced DNA-binding activity of p53. HHV-6B induced phosphorylation of p53 at Ser15 and Ser20 by casein kinase 1,¹⁷² suggesting that viral suppression of T-cell proliferation links to p53 phosphorylation and accumulation.²⁰⁹ p53 protein levels increase in HHV-6-infected cells, and p53 ubiquitination decreases, indicating that the deubiquitination increases p53 stability. p53 mainly localizes in the cytoplasm of HHV-6-infected cells, but it translocates into the nucleus of mock-infected cells. Infected cells are resistant to UV-induced apoptosis, suggesting that HHV-6 has a mechanism for retaining p53 within the cytoplasm, providing protection from apoptosis.²⁶⁶ Since HHV-6 gene expression is enhanced in the absence of active p53,²¹¹ p53 induction may be a cellular response to the invading pathogen. p53 interacts with the HHV-6B U14 tegument protein, and is incorporated into viral particles.²⁶⁵

Some parallels have emerged in studies of apoptosis induction during infections with HHV-6 and HHV-7. In fresh umbilical cord blood lymphocytes, infected cells are apoptotic,^{25,120} whereas in cell lines, infected cells die by necrotic lysis and apoptosis is triggered in apparently uninfected or nonproductively infected cells.^{124,240} The virus may be able to inhibit apoptosis in at least some cells and its replication might be enhanced by suppression of apoptosis. This was borne out experimentally for HHV-7 in cells expressing high levels of the apoptosis suppressor, Bcl-2.²³⁹ During *in vivo* primary HHV-6B infections, apoptosis was detected in 15% to 20% of circulating PBMC.³⁰⁹

HHV-6 attachment and/or entry in the absence of *de novo* protein synthesis can induce expression of the human endogenous retrovirus K18-encoded superantigen.^{260,288}

In HHV-6-infected immature monocyte-derived dendritic cells, viral early and late antigens are expressed, and nucleocapsids containing a DNA core are observed, but few virions are detected in the cytoplasm. In co-cultures, HHV-6 can be transmitted from these cells to stimulated CD4⁺ T cells, suggesting that DCs may be one of the first cell populations targeted by the virus and may transmit the virus to T cells.²⁶⁴

PATHOGENESIS AND PATHOLOGY

Detailed referencing of historical literature in this area is available in several comprehensive and recent reviews.^{34,86,217,297}

Transmission

HHV-6B and HHV-7 are ubiquitous viruses, with horizontal infection commonly occurring during infancy. HHV-6 DNA has been detected in saliva, throat swabs, and nasal mucous of children and their mothers, as well as other healthy adults, suggesting horizontal infection through saliva and nasal secretions. HHV-6 is also detectable in the female genital tract and on the cervix of pregnant women in the late stages of their pregnancies, suggesting the possibility of transmission to neonates during vaginal delivery. No difference was found in the prevalence rates of HHV-6 infection between breast- and bottle-fed infants or between babies born by cesarean section and vaginal delivery. Local or seasonal exanthem subitum outbreaks are rare, but have been observed in pediatric institutions.

Finally, other routes of horizontal transmission have been reported, such as via organ transplantation. HHV-6B was isolated from recipients about 2 weeks after liver transplantation, accompanied by significant rises in HHV-6 antibody titers,³¹⁷ suggestive of primary infection.

While most HHV-6 infections occur via horizontal routes, approximately 1% of the population acquires the HHV-6 genome via germline cells that trace to either or both of their parents.^{64,194,214,271} In such individuals, an intact HHV-6 genome is integrated at the telomere of a chromosome, with copies of that chromosome being present in every cell in the body. While HHV-6 DNA has been detected in fetuses and in blood of neonates, indicating that intrauterine transmission is possible, most cases of congenital transmission of ciHHV-6 can be attributed to either genetic transmission of ciHHV-6 from either or both parents or to transplacental transmission from mothers with ciHHV-6.^{108,111} In addition, HHV-6-positive dried umbilical cord blood spots were more common for babies born to HIV-positive mothers.⁶³

Infectious HHV-7 can be readily isolated from saliva of healthy adults.³⁰¹ Probable transmission of HHV-7 from grandparents to parents and to children through close contact within a household was detected by using molecular epidemiologic techniques.²⁶³ It has been speculated that breast-feeding may be a route for HHV-7 transmission, but this is not the main route.⁹⁴ Thus, HHV-7 transmission may follow pathways similar to that for HHV-6B, except that congenital HHV-7 infections have not been detected.^{44,109}

Primary Infection

Site of Primary Replication

HHV-6 and HHV-7 possibly initiate infection through respiratory pathways, including lymphocyte-rich tonsils and olfactory-ensheathing cells present in the nasal cavity.

Cell and Tissue Tropism

The *in vivo* host-tissue range of HHV-6 includes lymphoid and endothelial cells, as well as cells present in the liver, CNS tissues, and salivary glands.^{34,36,69}

In vivo, HHV-7 infects CD4⁺ T lymphocytes (believed to be the site of latent infection), and salivary gland epithelial cells (a site of productive infection and viral shedding).²⁸ In

addition, cells expressing an HHV-7 structural antigen were detectable in lungs, skin, and mammary glands, and at reduced frequencies in liver, kidney, and tonsils. This antigen was not detected in the large intestine, spleen, or brain.¹³⁹

Persistence

HHV-6 DNA and antigens can be detected in saliva, nasal secretions, brain, lung, bone marrow progenitors, and PBMC. HHV-6 DNA was detected mainly in the monocyte fraction of PBMC from patients convalescing from ES and from healthy adults, and appears to establish latency in monocytes or macrophages and CD34-positive progenitor cells.^{10,148,167} As described previously, latency-associated transcripts have been detected from the IE region and U94. In a prospective study, 89% of children from 1 to 12 years of age were PCR positive for HHV-6 at least at one time point, with 1.2% of specimens being positive for reverse transcription PCR (RT-PCR), indicating active infection.⁴⁷ This activity was not associated with illness.

The HHV-6 variants differ with respect to their absolute and relative frequencies of detection in PBMC and cerebrospinal fluid (CSF). Of over 1,000 HHV-6 PCR-positive PBMC specimens, 2.5% were positive for HHV-6A and 99% for HHV-6B (some were positive for both). Of 84 HHV-6 PCR-positive CSF specimens, 17% were positive for HHV-6A and 86% for HHV-6B (some dual positives). Thus, HHV-6B was detected much more frequently in CSF than was HHV-6A, but the ratio of 6A to 6B was higher in CSF than in PBMCs, indicating a greater relative neurotropism for HHV-6A.¹¹⁰

Germ line ciHHV-6 enables a form of persistence in which the virus genome is present in every cell in the body. Under most circumstances, the virus is apparently quiescent. It has been hypothesized that the default latency pathway for HHV-6 in individuals without germline ciHHV-6 involves chromosomal integration,¹⁷ but this has not been demonstrated.

HHV-7 establishes latent infections in CD4+ cells,⁹³ and persistent lytic infections in salivary glands.³⁰¹ As described previously, HHV-7 lytic antigens are present in a variety of tissues, suggesting that persistent infection occurs in many tissues *in vivo*.¹³⁹ None of three HHV-7 lytic cycle transcripts studied were detected in HHV-7 DNA-positive PBMC,¹⁸¹ evidence that the virus is truly latent in these cells.

Immune Response

Immune responses to HHV-6 and HHV-7, and their immunomodulatory activities, have been reviewed in detail.^{69,296,297}

Antigens

Responses are generated to many of the virally encoded proteins. The major HHV-6 antigen in immunoblots is a protein encoded by U11 (101K or p100). Responses to HHV-7 are directed predominantly to pp85 and pp89 (encoded by U14 and U11),²⁵² as well as to a 52-kd species.¹⁹⁵ Consistent with their sequence similarities, sufficient antigenic cross-reactivity exists between HHV-6A and HHV-6B to preclude the use of conventional serologic assays for the study of variant-specific immune responses. A recently described serologic assay appears to enable accurate variant-specific serology.²⁷⁵ Although a degree of antigenic cross-reactivity is seen, serologic assays can distinguish between responses to the HHV-6 species and HHV-7. These levels of cross-reactivity are reflected in the frequencies of cross-reactive mAb and T-cell clones.^{18,28,310}

Primary Infection

Serologic studies on the association between ES and HHV-6 infection have mainly come from Japan. In patients with ES, IgM antibodies were detected on day 5, and persisted for 3 weeks, but were not detectable in most sera 1 month after the onset of disease. IgG antibodies are first detected about 7 days after onset of illness, increase for 3 weeks, and persist thereafter (eFig. 64.6). The viremia during primary infection subsides coincident with the appearance of neutralizing antibodies. HHV-6 antibody titers are boosted during infection with HHV-7.^{134,270}

Cellular immunity appears to be important for control of primary HHV-6 infection. A T-cell immune response against HHV-6 is generally present in healthy adults.^{295,304} Some T-cell clones with activity against HHV-6 also responded to HHV-7 and HCMV, indicating the presence of shared T-cell epitopes.³¹⁰

Plasma IFN- α levels are elevated during the acute febrile phase of ES compared with convalescence.²⁶² NK-cell activity is also elevated in the exanthem phase of ES, probably induced by IL-15.^{88,262} These early responses likely play pivotal roles in control of the infection.

In *in vitro* studies, IFN- α activity was detected in PBMC from healthy seropositive adults as early as 12 hours after exposure to HHV-6; they plateaued at days 2 to 5, and gradually decreased thereafter. The response of cord blood mononuclear cells was lower.¹⁴² HHV-6 also induces IL-1 β and TNF- α , but not IL-6 in PBMC.⁸⁴ Thus, HHV-6 can exert a strong immunomodulatory effect by stimulating cytokine production in cells of myeloid lineage. IFN- γ regulates the production of IL-10 and IL-12 at a transcriptional level mainly through inhibiting endogenous IL-10 production in HHV-6-infected monocyte-macrophage cells.¹⁵⁹

Reports on the immune response during HHV-7 primary infection are scarce because HHV-7 primary infection is seldom apparent. During a documented infection, 16 days after onset, HHV-7 antibody titer rose from less than 1:10 to 1:320 by an immunofluorescence antibody (IFA) test, whereas the HHV-6 titer remained less than 1:10.²⁶⁸ In a patient with two independent ES episodes within 2 months, HHV-6 and HHV-7 were sequentially isolated; seroconversion to HHV-7 during the second episode was observed 4 days after disease onset. HHV-7 infection induces IL-15 production, which then results in an enhancement of NK-cell activity that may play a major role in control of the infection.²²

Immunomodulation

HHV-6 infects a variety of immune cells, as described previously, and has numerous immunomodulatory effects *in vivo* and *in vitro*.

Infection of PBMC or T-cell-enriched cultures by HHV-6A suppressed IL-2 synthesis after mitogen stimulation, and levels of IL-2 transcripts were diminished in experiments with enriched T-cell cultures or Jurkat cells.⁸⁵

Suppression of bone marrow function may be one of the most serious effects of HHV-6 infection in bone marrow transplant recipients. *In vitro*, HHV-6 infection of normal bone marrow mononuclear cells reduced the outgrowth of granulocyte-macrophage colony-forming units (GM-CFU), granulocyte-erythrocyte-macrophage-megakaryocyte colony-forming units (GEMM-CFU), erythroid burst-forming units, and marrow stromal cells by 40% to 74%.³⁹ Although HHV-6A was generally a more potent inhibitor than HHV-6B, it did

not exhibit as significant a suppressive effect on the formation of GM colonies. In hemopoietic progenitor cells derived from human umbilical cord blood lymphocytes, HHV-6A suppressed erythroid colonies, HHV-6B suppressed erythroid and GM colonies, and HHV-7 had no effect on either lineage.¹²⁸ These results could be the consequence of the virus either encoding or inducing a soluble mediator or mediators that interfere with the responses of bone marrow to growth factors and block differentiation of macrophages from marrow precursors.³⁹

An *in vivo* model for immune suppression by HHV-6 was developed in severe combined immunodeficient (SCID-hu) Thy/Liv mice.⁹⁹ HHV-6A and HHV-6B efficiently infected the human thymic tissue implanted in these mice, leading to graft destruction. Virus replication was associated with severe, progressive thymocyte depletion involving all major cellular subsets. Intrathymic T progenitor cells were more severely depleted than the other subpopulations, and a preferred tropism of HHV-6 for these cells was demonstrated. Thus, thymocyte depletion by HHV-6 may be caused by infection and destruction of their immature precursors.

HHV-6A and HHV-6B, but not HHV-7, modestly (two-fold) induced several T-cell adhesion markers, including CD2, CD4, CD11a, CD44, CD49d, and HLA antigen-DR. HHV-6B infection had little effect on CD4+ cytotoxic lymphocytes, but HHV-6A and HHV-7 decreased their activity; the inhibition by HHV-7 was overcome by lectin stimulation.⁹⁵ Thus, the three viruses differ in their effects on T cells.

Human lymphocyte antigen (HLA) class I expression on dendritic cells (DC) was downregulated after infection with HHV-6A but not HHV-6B, whereas no significant change was seen in the expression of CD1a, CD83, and MHC class II; IE or E gene expression was required for this.¹¹⁷ Preexposure to HHV-6 markedly impaired IFN γ - and lipopolysaccharide-induced DC maturation. HHV-6, but not HHV-7, dramatically suppressed the secretion of IL-12 p70 by DC, whereas the production of other cytokines that influence DC maturation (i.e., IL-10 and TNF- α) was not affected.²⁴⁹ Children who acquired HHV-6 after 18 months of age were more likely to express IgE to common allergens, suggesting that early life exposure to HHV-6 might reduce allergic responses, possibly due to the virus downregulating Th2 responses.²⁰² While HHV-6 infection led to reduced IL-5 expression in DC, systemic IL-5 levels are elevated during convalescence from primary infection.³¹⁸

HHV-6 infection of monocyte-derived immature DC induced CD80, CD83, CD86, and HLA antigen class I and class II molecules, but decreased their capacity to present alloantigens and exogenous virus antigens to T lymphocytes.¹³² Levels of DC-specific intracellular adhesion molecule-grabbing non-integrin (SIGN) messenger RNA (mRNA) and intracellular protein decreased following HHV-6 infection.²⁰⁰

The cytokine encoded by HHV-6A U83 is an agonist for CCR1, CCR4, CCR5, CCR6, and CCR8 present on immune effector and antigen presenting cells.^{48,76} HHV-6B U83 can induce transient calcium mobilization through the CCR2 receptor and serve as a chemoattractant for mononuclear cells.^{171,328}

HHV-6 and HHV-7 U12 and U51 encode GPCR homologs. HHV-6 pU12 is a functional β -chemokine receptor, with selectivity that differs somewhat from its cellular homologs in its higher affinity for RANTES relative to macrophage inhibitory proteins 1 α and 1 β or monocyte chemoattractant protein 1.¹²⁷ When stably expressed in cell lines,

HHV-6 U51 specifically binds the CC chemokine RANTES and competes for binding with other β -chemokines, such as eotaxin; and monocyte chemoattractant proteins 1, 3, and 4. In epithelial cells already secreting RANTES, U51 expression induces specific transcriptional downregulation of RANTES.¹⁸⁴ U51 constitutively activates phospholipase C. It also binds several chemokines and promotes chemotaxis and internalization of chemokines, suggesting roles in virus dissemination or host transmission by chemotaxis of infected cells to sites of chemokine secretion specific for U51.^{49,83} Suppression of U51 expression by siRNA reduces the replication of HHV-6, demonstrating that U51 is important for virus growth.³²⁶

HHV-7 U12 and U51 also encode functional calcium-mobilizing receptors for β -chemokines, which include thymus and activation-regulated chemokine, macrophage-derived chemokine, EBI1-ligand chemokine, and secondary lymphoid-tissue chemokine.^{196,259} Furthermore, EBI1-ligand chemokine and secondary lymphoid-tissue chemokine induce migration in Jurkat cells stably expressing U12, but thymus and activation-regulated chemokine, and macrophage-derived chemokine, do not.²⁵⁹

HHV-6A had little direct effect on cytokine production in primary adult astrocytes, but profoundly affected the response of these cells to a mixture of proinflammatory cytokines (TNF- α , IL-1 β , and IFN- γ), inducing anti-inflammatory molecules (IL10 and IL-11), chemotactic and growth factors, and regulators of type 1 IFN production.¹⁷⁹

HHV-6B IE1 is resistant to IFN- α/β antiviral activity as a result of improper IFN-stimulated gene (ISG) expression.^{129,130} HHV-6B IE1 interacts with STAT2 and sequesters it in the nucleus, preventing ISG3 from binding to IFN-responsive promoters. This results in silencing of ISG, suggesting that IE1 has a role in regulating cellular antiviral responses.

HHV-6 and HHV-7 U21 proteins bind to HLA class I molecules and divert them to endolysosomal compartment, thereby removing them from the cell surface, leading to reduced or delayed cytotoxic T-lymphocyte recognition of infected cells.^{98,119}

HHV-6 and HHV-7 U24 proteins cause internalization of the T-cell receptor/CD3 complex at the cell surface, resulting in improper T-cell activation by antigen-presenting cells.²⁵⁵ U24 also downregulates the transferrin receptor, suggesting that U24 acts by blocking early endosome recycling.²⁵⁶

Epidemiology

HHV-6 and HHV-7 epidemiology has been reviewed in depth elsewhere.^{28,34,69,297}

Serologic assays used to date do not enable discrimination of prior infections with HHV-6A from HHV-6B, but recently described assay appears to enable variant-specific serologic testing, which will hopefully enable many aspects of HHV-6A and HHV-6B epidemiology to be untangled. Infants appear to be protected against HHV-6 infection by maternal antibody. HHV-6 seroprevalence decreases from 0 to 5 months of age, as maternal antibody wanes. Beginning at about 6 months, seroprevalence increases rapidly, with almost all children becoming positive by 2 years of age.^{205,324} Internationally, HHV-6 seroprevalence is high in almost all areas, but ranges from approximately 39% to nearly 100% among some ethnically diverse adult populations. In the United States, Europe, and Japan, most early childhood infections are with HHV-6B,

rather than HHV-6A. The situation seems to be reversed in sub-Saharan Africa,²³ suggesting significant international differences in the epidemiology of HHV-6 variants. In areas where early childhood infections with HHV-6B predominate, HHV-6A has been detected by PCR in blood or tissues from as many as 50% of adults. Little is known of the course of such infections that occur in the face of preexisting immunity against the closely related species.

HHV-7 infection generally occurs somewhat later than for HHV-6.³⁰² As for HHV-6, seroprevalence declines over the first 5 to 6 months, as maternal antibody wanes, then increases fairly rapidly through about 4 years of age. It reaches its highest level from the teens until the end of the third decade, decreasing thereafter.^{269,315}

Clinical Features

Primary Infection

Exanthem subitum (ES) was first described in 1910 by Zahorsky³²² and is a common disease of infants internationally. In the classic presentation, an infant develops sudden fever, which lasts for a few days, followed immediately by a rash that appears on the trunk and face and spreads to lower extremities as the fever subsides. A virus was hypothesized as the cause. In experiments now considered unambiguously unethical, human-to-human transmission of the infection was observed following experimental inoculation of blood of patients with ES into other infants.^{114,138} Efforts to isolate the causative agent of ES were unsuccessful until the first report linking HHV-6 infection and ES by Yamanishi et al. in 1988.³⁰⁶ HHV-6 was isolated at high frequency from patients with ES during the acute phase of the disease. About 10 days after cultivation, a cytopathic effect (CPE) could be observed, which showed balloon-like cells. When cells were fixed and stained with sera during the acute and convalescent phases of ES, positive staining was observed only using convalescent sera (Fig. 64.2). Subsequent studies found that HHV-6 primary infection can occur without clinical symptoms of rash or fever, or even without any clinical symptoms. ES is caused by HHV-6B, and the magnitude of the virus replication in infants with ES is proportional to the severity of disease.¹⁹ In most cases, ES is self-limiting, and is often associated with other symptoms, including diarrhea, cough, lymph node swelling, and bulging fontanels. In adults,

primary infections can cause mononucleosis-like disease and hemophagocytic syndrome.

Although the frequency of clinical illness is lower, primary infection with HHV-7 causes illnesses similar to those caused by HHV-6, including ES, high fever, and neurologic symptoms (e.g., febrile convulsions).^{45,268,298} An example of successive bouts of ES caused by HHV-6 and then HHV-7 is illustrated in eFigure 64.7.

Symptoms Associated with Primary Infection

The pathogenesis of HHV-6B primary infection is illustrated in Figure 64.7.

The most commonly reported severe symptom associated with ES is febrile convulsion, which generally has a benign resolution. In a large study, Hall et al.¹¹² found that of the 160 infants and young children with acute HHV-6 infection, 21 (13%) were hospitalized, and 21 had seizures. The seizures often appeared late and were prolonged or recurrent. HHV-6 infections accounted for one third of all febrile seizures in children up to the age of 2 years. In this study, 7 (24%) of 29 CSF specimens were positive for HHV-6 by PCR, including 2 of 7 from children with convulsions. HHV-6 DNA was also detected in CSF from patients with neurologic manifestations at the time of primary infection of HHV-6.^{46,254,319} In contrast with the frequency of HHV-6 in CSF during clinically apparent acute episodes, in a prospective study, no seizures were reported among children who had a well-defined time of primary infection.³²⁴ HHV-6 persists in the CNS and has been reported to increase the risk for recurrence of febrile convulsions.¹⁴⁹ A recently reported prospective study, however, suggests that a first febrile seizure associated with an acute HHV-6 infection may be associated with a reduced risk for recurrent seizures.¹³¹

Encephalitis/meningoencephalitis/encephalopathy can occur during primary HHV-6 infection. Of 89 cases identified in a Japanese national survey, half of the patients had neurologic sequelae and 2 died.³²⁰ In comparison to stem-cell recipients, HHV-6 encephalitis during primary infection is characterized by low viral DNA levels in the CSF and differences in cytokine responses.¹³⁷

Liver dysfunction is also associated with HHV-6 infection; although usually mild, fatal hepatitis and chronic hepatitis have been also reported.^{21,261} Primary HHV-6 infection has

Transmission

- Close contact through saliva (major route)
 - Mother to children
 - Siblings (at home)
 - Among infants (at day care center)
- Congenital infection
 - Transplacental
 - ciHHV-6

Major clinical symptoms of ES

- | | | |
|---------------|---|---------------|
| Fever | → | Convulsions |
| CNS infection | → | Encephalitis |
| Lymph node | → | Lymphadenitis |
| Skin | → | Rash |
| Liver | → | Hepatitis |

FIGURE 64.7. Pathogenesis of HHV-6B primary infection.

also been associated with cases of idiopathic thrombocytopenic purpura.^{143,247}

Primary HHV-7 infection can cause febrile illness, sometimes complicated by seizures and acute hemiplegia.²⁹⁸

Neurologic symptoms accompanying primary HHV-6 and HHV-7 infections sometimes occur in temporal coincidence with childhood vaccinations, leading to the likely incorrect conclusion that the vaccine caused the illness.²⁹⁸

Disease in Immunocompromised Patients

Because herpesviruses persist in their hosts after primary infection and can be reactivated, they are important pathogens in immunocompromised hosts. Exogenous reinfections are also possible and may contribute to disease in such patients.⁶

BONE MARROW TRANSPLANT RECIPIENTS

Asymptomatic HHV-6 reactivation is common after allogeneic bone marrow or hematopoietic cell transplantation, but reactivation has also been linked to bone marrow suppression, encephalitis, delirium and neurocognitive decline, gastroenteritis, colitis, pneumonitis, rash, and acute graft-versus-host disease (GVHD).^{34,60,69,115,292} In skin and rectal biopsy specimens from 34 allogeneic bone marrow transplant (BMT) recipients and 23 autologous recipients, HHV-6 DNA was detected in PBMC of 74% of autologous and 76% of allogeneic recipients, and in biopsy tissue of 48% of autologous and 71% of allogeneic recipients.¹³ HHV-6 DNA was detected more frequently in allogeneic recipients with severe GVHD (92%) than in those with either moderate (55%) or mild GVHD (22%), suggesting that the presence of HHV-6 DNA in the skin or rectum may be a factor in determining GVHD severity.

HHV-6 infection has also been associated with pneumonitis, with the infected cells being primarily intra-alveolar macrophages, plus some lymphocytes.³⁸ Concentrations of HHV-6 genomes in lung tissue and their relation to changes in serologic titers support an association between HHV-6 infection and idiopathic pneumonitis in immunocompromised hosts.⁵⁹

Prospective monitoring and prophylactic antiviral strategies for prevention of roseolovirus-associated disease have not been recommended in formal practice guidelines.^{164,323}

SOLID ORGAN TRANSPLANT RECIPIENTS

Children seronegative for HHV-6 before transplantation rejected their kidneys early after transplantation,²⁹⁴ and HHV-6 has been associated with kidney rejection.^{4,204,321} About 30% of renal transplant recipients showed a significant increase of serum antibody titer against HHV-6 after transplantation, all of whom suffered severe kidney rejection. HHV-6 antigens were detected in the tubular epithelium as well as in infiltrating histiocytes and lymphocytes. The frequency of HHV-6 and/or HHV-7 plasma DNA was significantly higher in chronic allograft nephropathy (CAN) patients (25/28, 89.3%) compared to control patients (15/50, 30.0%, $p = 0.0001$).⁵² CAN patients also had more frequent dual active infections (20/25, 80% and 2/15, 13.3%, $p = 0.007$, respectively). HHV-6B was identified in all 34 HHV-6 positive cases. The presence of HHV-7 DNA in plasma preceded the presence of HHV-6 DNA. Early development of CAN and graft loss was detected only in patients with simultaneous HHV-6 and HHV-7 plasma DNA.

The relationship between clinical features and HHV-6 infection has been investigated in liver transplant recipients.^{246,247}

HHV-6 infection occurred in four liver transplant recipients a median of 50 days after transplantation, accompanied by severe cytopenia. One of the four patients had interstitial pneumonitis caused by HHV-6. These authors suggest that idiopathic bone marrow suppression is the predominant clinical sequelae of HHV-6 in these patients. One liver transplant recipient experienced an acute febrile illness with life-threatening thrombocytopenia, progressive encephalopathy, and skin rash in association with invasive HHV-6B infection. Liver transplant recipients with ciHHV-6 experienced more bacterial infections and allograft rejection than those without ciHHV-6.¹⁵⁷

HHV-6, HHV-7, and HCMV may cause some symptoms by reactivating doubly and triply.^{74,106,208,222}

The AST Infectious Diseases Community of Practice has made the following statements: solid organ transplant recipients should not be routinely monitored for roseoloviruses, asymptomatic viral activity does not warrant antiviral treatment, antiviral therapy (intravenous ganciclovir or foscarnet) should be initiated for HHV-6 encephalitis and other more serious syndromes associated with the virus, treatment should include reduction of immunosuppression, and prophylactic and preemptive antiviral therapy are not recommended.^{223–225}

ACQUIRED IMMUNODEFICIENCY SYNDROME (AIDS)

The possible role of HHV-6 as a co-factor in HIV infection has been considered because both viruses can infect CD4⁺ cells, and HHV-6 can transactivate the HIV LTR.³⁴ Furthermore, HHV-6 can induce CD4 gene transcription and expression in CD4-negative cells, which renders them susceptible to HIV infection. It has been hypothesized that the most important issue with respect to HHV-6–related disease in HIV-positive individuals may not be a direct effect on specific target organs, but by HHV-6 contributing to immunodeficiency.¹⁶⁹

Comparisons between patients infected with HIV and uninfected controls have shown either no difference in seroprevalence and titer or higher or lower prevalence among those infected with HIV. The detection rate of HHV-6 DNA in PBMC and saliva has also been variable. Two studies found no correlation of HHV-6 seroprevalence with progression to AIDS, whereas another found that patients whose disease progressed slowly had decreased HHV-6 seroprevalence compared with those whose disease advanced rapidly. A marked association was seen between HHV-6 infection and progression of HIV disease in Thai children.¹⁵²

Lung infection with HHV-6 was sufficiently extensive in one patient to account for fatal pneumonitis. In other tissues, increased numbers of HHV-6–infected cells were related to the presence of lymphocyte infiltrates or residual lymphoid tissue, with lymphocytes being predominantly infected.¹⁴⁵ HHV-6–associated retinitis has been seen in patients with AIDS.²²⁰ HHV-6 was more extensively disseminated in neural cells of brains of pediatric patients with HIV, suggesting a contribution to the pathogenesis of AIDS encephalopathy.²³² Adult patients with AIDS had areas of demyelination in their CNS tissue at the time of death.¹⁴⁶ The presence of HHV-6 in an organ was significantly associated with an elevated HIV-1 proviral load.⁸¹

Co-infections of macaques with HHV-6A and simian immunodeficiency virus (SIV) resulted in a plasma viremia that was associated with clinical manifestations that progressed to AIDS more rapidly than in monkeys infected only with SIV,

providing *in vivo* evidence that HHV-6A may promote AIDS progression.¹⁶⁸

POSSIBLE DISEASE ASSOCIATIONS

Neoplasia. HHV-6 DNA has been detected in non-Hodgkin's lymphoma, Hodgkin's disease, S100-positive, T-cell chronic lymphoproliferative disease, oral salivary gland carcinoma tissues, pediatric and adult glial tumors, and other neoplasias.^{34,61,62,303} Although there has been no conclusive demonstration that either HHV-6A or HHV-6B is involved in a causative way with any malignancy, the frequency of detecting HHV-6 in certain tumors suggests a possible co-factorial role in multistep carcinogenesis.

Chronic Fatigue Syndrome. Conflicting reports have appeared of a connection between chronic fatigue syndrome (CFS) and HHV-6 infection. We do not consider the evidence to be supportive of an etiologic association.

Multiple Sclerosis and Other Neurologic Disorders.

Numerous studies have found that HHV-6B is a commensal virus of the human brain. The high prevalence of the virus in the olfactory bulb suggests that a route of CNS entry might be via olfactory ensheathing glial cells present in the nasal cavity.¹¹³

Multiple sclerosis (MS) is characterized clinically by neurologic signs and symptoms that wax and wane over time and involve multiple nerve pathways. Several studies have suggested an association between HHV-6 and MS, but the association remains uncertain.²⁹³ Staining of neurons and oligodendrocytes in plaque regions was observed in MS patients using mAb against HHV-6 virion protein 101K and DNA-binding protein p41.⁵¹ Elevated IgM serum antibody responses to HHV-6 early antigen (p41/38) were found in patients with relapsing-remitting MS, compared with patients with chronic progressive MS, other neurologic disease, other autoimmune disease, and with controls.²⁵⁰ HHV-6 DNA was detected with high frequency in MS plaques isolated by laser microdissection⁵⁰ and in neurologic and inflammatory cells in acute-phase lesions tissue of MS.¹⁰² Viral DNA and infectious virus was detected in CSF collected early in the course of MS,²²⁸ and viral transcripts were detected at higher levels in brains of patients with MS,²⁰⁷ with the highest loads being in lesional tissues. HHV-6 activity in MS patients has also been associated with poor response to interferon β 1b treatment⁹⁶ and a particular allele of an MHC regulatory gene.⁹

Negative results, however, were obtained in other studies.²⁹³ No significant difference was found in detection of HHV-6 DNA in sera and CSF between groups of patients with MS, patients with other neurologic diseases, and controls.⁸² Furthermore, no significant difference was seen between patients with MS and patients not having MS by immunohistochemical staining of brains or by PCR of defined brain regions.^{57,287} Further experiments are needed, including multicenter evaluation of blinded, carefully defined specimens.

HHV-6 has been detected in CSF from patients with encephalitis. In some patients, HHV-6 antibody and CSF DNA levels increased during the disease.³⁰⁷ In addition, herpes simplex encephalitis and HHV-6-associated encephalopathy give markedly different patterns as visualized by computerized tomography or magnetic resonance imaging.²⁰¹ In some instances, the HHV-6/encephalitis association was probably a nonspecific finding that resulted from the affected individual harboring ciHHV-6.

HHV-6 DNA has been detected in resected brain tissues from patients with mesial temporal lobe epilepsy.^{161,276} In one study, this association was restricted to patients with history of encephalitis.¹⁹⁹

Progressive multifocal leukoencephalopathy (PML) is a primary demyelinating disease of the CNS occurring almost exclusively in individuals with impaired cell-mediated immunity. The JC polyoma virus has been accepted as the etiologic agent of PML. Using a two-step *in situ* PCR procedure to amplify and detect genomic DNA of HHV-6 in formalin-fixed paraffin-embedded archival brain tissues, a high frequency of infected cells was consistently detected in PML white matter, both within and surrounding demyelinating lesions, the HHV-6 genome being found mainly within oligodendrocytes. Lesser amounts of HHV-6 genome were detected in tissues of patients with AIDS, patients with other neurologic disease, and controls. Immunocytochemistry for HHV-6 antigens showed actively infected nuclei of swollen oligodendrocytic morphology within the demyelinating lesions of PML but not in adjacent uninvolved tissue. In addition, HHV-6 antigens were not detectable in control tissues, including brains of patients with HIV-1 encephalopathy but without PML. Double immunohistochemical staining for JC virus large T antigen and HHV-6 antigens demonstrated co-labeling of many swollen intralosomal oligodendrocytes in the PML cases. Thus, HHV-6 activation in conjunction with JC virus infection is associated with the demyelinating lesions of PML.¹⁸⁷

Myocarditis. Laboratories in Europe and Japan have reported detection of HHV-6 DNA in affected heart tissues from children and adults with acute myocarditis.^{11,58,173}

Drug Hypersensitivity. Drug-induced hypersensitivity syndrome is characterized by a severe, potentially fatal, multiorgan reaction that usually appears after prolonged exposure to certain drugs.²⁸⁰ Clinical features overlap those for Stevens-Johnson syndrome and toxic epidermal necrolysis. Clinical signs include a maculopapular rash progressing to exfoliate erythroderma, fever, and lymphadenopathy. Reactivation of herpesviruses—including HHV-6B, HHV-7, HCMV, and EBV—have been detected during severe drug-induced hypersensitivity syndrome and the related illnesses,^{258,281} but it is uncertain whether the virus reactivation causes the disease, is triggered by the disease, or contributes to the disease.

Pityriasis Rosea. Pityriasis rosea was reported to be associated with HHV-7 infection,⁸⁰ but the association was not seen in other investigations.^{140,300}

Animal Model

Animal models for roseolovirus infections have been developing slowly. HHV-6 antibodies have been found in several species of monkeys, suggesting the presence of HHV-6 or an HHV-6-related virus.¹¹⁶ Related viruses were subsequently detected by PCR in mandrills and chimpanzees.^{155,156} PBMC from chimpanzees are permissive to productive HHV-6 infection *in vitro*, indicating that the host range of HHV-6 may not be restricted to humans.¹²⁹ In addition, cynomolgus and African green monkeys inoculated with HHV-6 developed antibody responses and HHV-6 DNA was detected in lymph nodes and spleens.³⁰⁵ The infection was asymptomatic, except for one monkey with rash.

Diagnosis

Diagnosis of HHV-6 and HHV-7 infections has been reviewed comprehensively elsewhere.^{34,215,217,297}

Differential Diagnosis

Because ES and the other symptoms associated with primary HHV-6 and HHV-7 infections are generally mild and self-limiting, specific laboratory diagnosis is seldom warranted in these children. Nonetheless, these viruses warrant inclusion in panels of agents to be investigated in cases of neurologic complications, particularly if the child was recently vaccinated.^{297,298} In some parts of the world primary HHV-6 and HHV-7 infections are occasionally misdiagnosed as measles or rubella virus infections.^{26,206} Roseoloviruses may also be considered in immunocompromised patients experiencing any of the wide variety of symptoms described earlier, including pneumonitis, fever, rash, GVHD, and CMV disease.

After early childhood, most individuals harbor latent infections with these viruses; latent infections have not been clearly associated with any disease. The diagnostic challenge is in distinguishing virus activity against the latent background. This is often facilitated by comparing paired acute and convalescent specimens, or consecutive specimens in patients who are being monitored closely, such as organ transplant recipients. Viral activity can be detected as changes in status, as measured by quantitative PCR or serologic titers. Direct evidence of active infection includes detection of infectious virus in cultured cells, lytic antigens in circulating lymphocytes or in affected tissues, transcripts of lytic cycle genes by RT-PCR, or viral DNA in acellular fluids such as plasma or serum.^{217,297} Recent infections can be identified through the use of antibody avidity assays, which differentiate the high avidity antibody that develops over 2 or so months following primary infection, from the sometimes high-titered but low-avidity antibody that develops in the days and weeks immediately following primary infection.²⁹⁷

VIRUS DETECTION

Culture. HHV-6 is easily recovered from PBMC of patients with ES during the acute phase. Lymphocyte activation with either PHA or antibody to CD3 and maintenance in IL-2 is required.³⁰⁶ CPE develops within 7 to 10 days, as shown in Figure 64.2. The refractile giant cells usually contain one or two nuclei; after CPE develops, the cells degenerate. Mononuclear cell-associated viremia caused by HHV-6 was detected in 66% of blood samples from children with ES between days 0 and 7 of the disease. The rate of virus isolation from mononuclear cells was 100% on days 0 to 2 (just before appearance of skin rash), 82% on day 3, 20% on day 4, 7% on days 5 to 7, and 0% on day 8 and thereafter. Cell-free virus was also detected in blood samples during the same period.²⁰ HHV-7 is sometimes isolated from peripheral blood of patients with ES, and can be readily isolated from saliva by using methods as described earlier for HHV-6. Isolation of HHV-6 from saliva is uncommon, although its DNA is often detectable there.

Detection of Viral Genome, Transcripts, and Proteins.

HHV-6 and HHV-7 DNA are commonly detected by quantitative polymerase chain reaction assays (qPCR). Numerous primer sets have been described, including rapid quantitative assays that enable identification and discrimination of HHV-6A and HHV-6B, simultaneous detection of HHV-6 and

HHV-7, and multiplex assays for all of the HHV.^{141,160,185,230} Loop-mediated isothermal amplification can also be used to detect HHV-6 and HHV-7 DNA.^{121,316} A monoclonal antibody-based quantitative antigenemia assay enables enumeration of HHV-6B-infected cells and has been used to monitor HHV-6 activity in liver transplant recipients.¹⁶⁶

A multicenter external quality assessment among 51 laboratories that employ PCR for HHV-6 found that most labs use in-house quantitative assays, there was good qualitative agreement on specimens containing at least 200 copies/mL, and quantitative reporting was much more variable.⁷¹

Latent and replicating virus can be discriminated by assays that combine reverse transcription and PCR (RT-PCR).^{203,314} Such assays target spliced mRNAs, enabling easy discrimination between mRNA (short amplicon because of intron removal) and residual DNA contamination (long amplicon). Because HHV-6 DNA is usually cell associated,² it can be more useful to describe qPCR results in terms of a ratio between virus and cell genomes, rather than in terms of virus genome copies per volume of fluid (e.g., virus genomes per mL of blood) that can contain variable concentrations of cells.⁹⁷

HHV-6 DNA is easily detectable by PCR in peripheral blood of patients with ES during the acute phase. Although detection of cell-free virus in serum or plasma by PCR offers the possibility of diagnosing active HHV-6 infections, PCR-based assays of plasma were not reliable for discriminating primary HHV-6 from ciHHV-6.⁴³ qPCR was less sensitive than culture for detecting primary infection, while RT-PCR was approximately as specific as culture for detection of primary infection.

ciHHV-6 presents several challenges to PCR-based methods for HHV-6 diagnosis.^{56,214,299} Because at least one copy of the virus genome is present in every cell, uncommonly high copy numbers will be detected in most clinical specimens, even if the virus is not actively replicating or otherwise contributing to the illness. Sufficient viral DNA can leak from lysed cells to cause false-positives in bodily fluids that are normally relatively acellular. Cell lysis during serum clotting and during the period between blood collection and plasma separation can also lead to false positives in these acellular fluids. ciHHV-6 should be suspected when uncommonly high levels of HHV-6 DNA are found. Persistent loads >5.5 log₁₀ copies/mL are consistent with ciHHV-6.²¹⁴

Serology

Numerous HHV-6 and HHV-7 serologic assays have been described,^{34,215,217} including IFA, anticomplement IFA, enzyme-linked immunosorbent assay (ELISA), neutralization (NT), radioimmunoprecipitation, and immunoblot; IFA is the most commonly applied method, with HHV-6-infected cells being used as the antigens. For detection of IgM, separation of serum IgM from IgG and IgA significantly increases the specificity, but IgM testing is not useful for clinical diagnosis.⁷² The products of U11 (86 kD) and U14 (85 kD) were identified as sensitive and specific markers for HHV-7 serology.²⁵² In a comparison of immunoblot, IFA, and ELISA assays for HHV-7 antibodies, the ELISA was the most sensitive, whereas the immunoblot was the most specific.³⁰ As mentioned, antibody avidity assays enable identification of recent primary infections.²⁹⁷ Serologic responses to HHV-6A and HHV-6B cannot be discriminated by the assays described earlier. A recently described assay appears to enable variant-specific serologic testing.²⁷⁵ Materials

for HHV-6 and HHV-7 IFA are available commercially, and testing is also available from commercial reference laboratories. Sources are listed in.²¹⁷

Prevention and Control

In immunocompromised patients, reduction of immunosuppression can improve immune control of roseolovirus infections.²²⁵ The European Conference on Infections in Leukaemia provided evidence-based guidelines for management of roseolovirus infections in patients with hematologic malignancies and after hematopoietic stem cell transplantation (HSCT).¹⁶⁵

Inhibitors of Replication

Ganciclovir, phosphonoformate (foscarnet) and cidofovir are potent inhibitors of roseolovirus replication *in vitro*, and are used clinically to treat these viruses. Acyclovir (ACV) and other thymidine kinase-dependent drugs are only marginally effective.^{34,69} The inhibitory effects of IFN- α and IFN- β on HHV-6 replication were also demonstrated *in vitro*, as described earlier. Ganciclovir is activated by the phosphotransferase encoded by gene U69, which can confer ganciclovir susceptibility on recombinant baculoviruses.¹² Methods have been described for rapid identification of U69 mutations in instances of clinical resistance to ganciclovir.¹²⁵ Other compounds with *in vitro* activity against HHV-6 include CMV423, a protein tyrosine kinase inhibitor,⁶⁶ and artesunate.¹⁸³ The sensitivity of HHV-7 to the guanine analogs was different from HHV-6, suggesting a difference in selectivity of specific viral enzymes.³¹³

PERSPECTIVES

Experimental study of the roseoloviruses has been hampered by several factors, including the difficulty of preparing high-titered, cell-free virus; the availability of relatively few monoclonal antibodies; lack of a useful animal model system; and no convenient system for genetic manipulation of the viruses. Fortunately, progress has been made on these fronts. Several interesting features of these viruses have been identified, including the ability of HHV-6 to be transmitted in a germline chromosomally integrated form; the presence near the viral genomic termini of arrays of sequences (terminal resolution site [TRS]) that are similar to sequences found at mammalian telomeres; the presence in HHV-6A and HHV-6B genomes of a homolog of a parvovirus replication or/regulatory protein; the presence of an OBP homolog and cognate-binding sequences that are similar to those previously found only in the alphaherpesviruses; effects on host-cell metabolism different from those described for other herpesviruses; presence of the key cell regulatory protein p53 in HHV-6 virions; and the expression of virally encoded functional GPCR. We anticipate that the implications of these observations will stimulate further study, and that other novel aspects of the biology and molecular biology of these viruses will be identified in future studies. Although the genomic sequences of these viruses are known, the functions of most viral gene products of HHV-6 and HHV-7 have not yet been elucidated. Exploitation of the recently described recombinant virus system for HHV-6A and its extension to HHV-6B and HHV-7 are needed to enable detailed examination of functions of the viral genes in the context of infection.

Much of the pathogenesis associated with roseolovirus infections is still undefined. Although the main routes of transmission of HHV-6 and HHV-7 appear to be via close contacts between infants and parents or siblings through saliva, alternative paths (e.g., vertical transmission) require additional study, and an explanation is still needed for primary HHV-7 infection generally following HHV-6, although infectious HHV-7 is present in abundance in saliva. Numerous questions remain about the role of integrated genomes in HHV-6 biology and their effect on the host. Widespread application of a recently described serologic assay will enable delineation of aspects of HHV-6A and HHV-6B epidemiology that have been hidden.

The mechanisms by which HHV-6 and HHV-7 regulate latency are not known. With man as the only host for HHV-6 and HHV-7, the identification of relatives of these viruses in nonhuman primates opens the window to developing animal models suitable for learning the *in vivo* functions of viral genes and for closer examination of pathogenic processes.

The high prevalence of the Roseoloviruses, coupled with their ability to establish life-long infections and their relatively low associated morbidity and mortality, suggest that these highly evolved viruses have much left to teach us about host-pathogen interactions.
